DEDICATION

I want to dedicate this work to my mother, Maria Louise Perello (1955-2015). My mother encouraged me to take every opportunity to explore the world and to try new things, including taking the big leap to start this doctorate. She is dearly missed, but her faith and love lives on.

ACKNOWLEDGEMENT

I first would like to acknowledge all of the support that I have received from my advisor, Dr. Broxton Bird. I am thankful for field assistance and support for this project provided by the Institute for Tibetan Plateau Research. I appreciate the opportunity to be a part of this exciting work and will remember these experiences for my entire life. It has been a tremendous privilege to visit Tibet and meet the amazing people that live and work there.

I want to thank all of my family for their tremendous support of me throughout my education. I would not be able to have completed this degree without their help, particularly Dad and his first-class pet sitting services.

I want to thank all of the faculty, staff and my fellow students in the Department of Earth Sciences, especially my committee, Cheryl Montgomery and Cathy Chouinard, for their support. Appreciation for research assistance to Dr. John Southon and the W.M. Keck Carbon Cycle AMS Laboratory, Dr. Mark Abbott and his students in at the University of Pittsburgh, and Dr. Byron Steinman at the Large Lakes Observatory. I am especially grateful for Dr. Pratigya Polissar and Sam Phelps for all of their help with preparing and running our leaf-wax samples at Lamont Doherty Earth Observatory. Thank you for making me feel welcome and supporting this research.

I wish to acknowledge that funding for this project was provided by the National Science Foundation (Award #1405072).

Melanie Marie Perello

RECONSTRUCTING HOLOCENE INDIAN SUMMER MONSOON VARIABILITY
USING HIGH RESOLUTION SEDIMENTS FROM THE SOUTHEASTERN TIBET

The Indian summer monsoon (ISM) is the dominant hydrometeorological phenomenon that provides the majority of precipitation to southern Asia and southeastern Tibet specifically. Reliable projections of ISM rainfall are critical for water management and hinge on our understanding of the drivers of the monsoon system and how these drivers will be impacted by climate change. Because instrumental climate records are limited in space and time, natural climate archives are required to understand how the ISM varied in the past in response to changes in climatic boundary conditions. Lake sediments are high-resolution natural paleoclimate archive that are widely distributed across the Tibetan Plateau, making them useful for investigating long-term precipitation trends and their response to climatic boundary conditions. To investigate changes in monsoon intensity during the Holocene, three lakes were sampled along an east-west transect in southeastern Tibet: Galang Co, Nir'Pa Co, and Cuobu. Paleoclimate records from each lake were developed using isotopic (leaf wax hydrogen isotopes; $\delta^2\text{H}$), sedimentological, and geochemical proxies of precipitation and lake levels. Sediments were sampled at high temporal frequencies, with most proxies resolved at decadal scales, to capture multi-decadal to millennial-scale variability in monsoon intensity and local hydroclimate conditions. The ISM was strongest in the early Holocene as evidenced by leaf-wax *n*-alkane $\delta^2\text{H}$ at both Cuobu and Galang Co corresponding with Cuobu's higher lake levels and effective moisture. Monsoon intensity declined at Cuobu and Galang Co around 6 ka which corresponds to reduced riverine sediment influxes at Cuobu and deeper lake levels at Galang Co. The antiphase relationship between lake levels and monsoon intensity at Galang Co is attributed to air temperatures and effective moisture, with a warmer and drier local hydroclimate driving early Holocene low lake levels. The late Holocene ISM was more variable with wet and dry periods, as seen in the Nir'Pa Co lake level and leaf wax *n*-alkane $\delta^2\text{H}$ record. These records demonstrate coherent drivers of synoptic and local hydroclimate that account for Holocene ISM expression across the southeastern Tibetan Plateau, indicating possible drivers of future monsoon expression under climate change.

LIST OF FIGURES

Figure 2.1. The location of Nir’Pa Co (NPC; red circle) in reference to other regional climate records. Lake sediment archives including El Junico (EJ), Lake Zigetang (LZ), Pallcacocha (PA), Paru Co (PC), and Selin Co (SC) are represented with circles. Cave records from Dongge Cave (DC) and Qunf Cave (QC) are represented with squares. The Dunde ice core (DU) is represented with a triangle. Marine sediment cores from the Arabian Sea (AS), Eastern Pacific (EP), and the Western Pacific (WP) are represented with stars. The Lhasa weather station (LH) is marked with an open circle	42
Figure 2.2. The Nir’Pa Co watershed and surrounding area with the lake at the end of a 5 km long glacially carved valley. Digital elevation data is from the USGS SRTM (Shuttle Radar Topography Mission) dataset and is shown in 100 m contour intervals.....	43
Figure 2.3. Bathymetric map of Nir’Pa Co with 2 m contour intervals. The respective core sites for A-11, A-15, and B-15 are designated with red circles. Location of the inlet and outlet to the lake are marked with the location of the moraine that terminates the watershed.....	44
Figure 2.4. Monthly total precipitation (mm \pm s.d.) and average temperature ($^{\circ}\text{C} \pm$ s.d.) at the Lhasa weather station. The monsoon season (May-September) is marked with a shaded gray	45
Figure 2.5. Total concentration of extracted long-chain C23 – C31 <i>n</i> -alkanes from sediment samples (ng/100 μL ; A- E). Terrestrial lipid distribution as indicated with the Carbon Preference Index (CPI; F), Average Chain Length (ACL; G), and the aquatic vegetation index (P_{aq} , H). Vertical black lines indicate the average value. The LIA and MCA time periods are marked with light blue and dark blue backgrounds (indicating wetter conditions) while 2250-1250 BP is marked with red background (indicating drier conditions).....	46
Figure 2.6. Leaf wax $\delta^2\text{H}$ (‰ VSMOW) $\pm 1 \sigma$ s.e.m. for C23 (A), C25 (B), C27 (C), C29 (D), and C31 <i>n</i> -alkanes. $\Delta\delta_{\text{C23-C31}}$ shows the variation between isotopic values between nC23 and nC31 (F). A more positive $\Delta\delta$ value indicates higher evaporation while a more negative $\Delta\delta$ indicates lower evaporation. Vertical black lines indicate average values. The LIA and MCA time periods are marked with light blue and dark blue backgrounds (indicating wetter conditions) while 2250-1250 BP is marked with red background (indicating drier conditions).....	47
Figure 2.7. Nir’Pa Co $\delta^2\text{H}$ nC23 (‰; A), $\delta^2\text{H}$ nC31 (‰; B), $\Delta\delta_{\text{C23-C31}}$ (‰; C), P_{aq} (D), and sand grain size (%; E). Compared with local climate records from Paru Co sand (%; F), principal components (G), $\delta^2\text{H}$ for nC27 and nC29 (‰; H), Seling Co $\delta^{18}\text{O}$ (‰; I), Lake Zigetang pollen index (J), and Dunde ice core $\delta^{18}\text{O}$ (‰; K). Vertical black lines indicate the average value for each proxy. The LIA and MCA	

time periods are marked with light blue and dark blue backgrounds (indicating wetter conditions) while 2250-1250 BP is marked with red background (indicating drier conditions).....48

Figure 2.8. Comparison of Nir’Pa Co $\delta^2\text{H}$ nC31 (‰; A) and $\Delta\delta_{\text{C23-C31}}$ (B) data with regional monsoon records and global forcing. Regional monsoon records include Dongge Cave $\delta^{18}\text{O}$ (‰; C), Qunf Cave $\delta^{18}\text{O}$ (‰; D), and Arabian Sea marine core $\delta^{18}\text{O}$ (‰; E). Pacific records include El Junico sand grain size (%; F), Pallcacocha red sediment color intensity (G), Eastern (H) and Western Pacific (I) and Indian Ocean (J) SSTs (Sea Surface Temperatures °C). Vertical black lines indicate the average value for each proxy. The LIA and MCA time periods are marked with light blue and dark blue backgrounds (indicating wetter conditions) while 2250-1250 BP is marked with red background (indicating drier conditions).....49

Figure 3.1. Bathymetric map of Cuobu with core sites marked (red colored dots with core names). Bathymetry mapped with 0.5 m contour intervals. Inlets and outlets to the lake are marked with blue dashed lines and arrows. Cuobu River is marked with a blue dashed line. Grey background and black dashed line designate the extent of a moraine between Cuobu and Cuobu River. A delta feature on the moraine is present where an ephemeral stream bed cuts across the moraine79

Figure 3.2. Topographic map of the area surrounding Cuobu, inset with the lake bathymetry (A). Cuobu watershed is designated with an orange dashed line. Topographic contours are at 50 m intervals while bathymetric contours are at 0.5 m intervals. An ephemeral stream (ii) and its delta (iii) that cut across the moraine are identified with a black box and shown in greater detail (B). The Cuobu River (i) is to the east of a moraine that forms the southeastern edge of Cuobu (iv). A transect (red dashed line) across the moraine is used to show the elevational profile (C) of the lake-moraine-river environment (B). The elevational profile is marked with red lines show the elevational difference between features.....80

Figure 4.13. Galang Co sand 5 pt. MA (‰; A) and $\delta^2\text{H}_{\text{C}_{23}}$ (‰; B) compared with records from the broader ISM extent, the East Asian Monsoon, and the El Niño-Southern Oscillation. Records include Dongge Cave $\delta^{18}\text{O}$ (‰; C), Mawmluh Cave $\delta^{18}\text{O}$ (‰; D), Qunf Cave $\delta^{18}\text{O}$ (‰; E), Eastern Pacific SSTs (°C; F), El Junco sand (‰: G), and Pallcacocha (red color intensity). Grey background represents low lake level stand (12.5-6 ka) at Galang Co. Vertical lines denotes average values over each record. Red and blue backgrounds indicate shallow and deeper lake conditions respectively130

1. INTRODUCTION

The Indian summer monsoon (ISM) is one of the largest and most crucial hydrometeorological systems in the world, with over 40% of the world's population living in its domain (Gadgil et al., 2004). The ISM serves as the dominant source of growing season precipitation on the Tibetan Plateau and surrounding region (termed the Third Pole; Qui, 2008), delivering ~80% of South Asia's precipitation (Sinha et al., 2015). Major rivers with headwaters in the plateau, including the Ganges, Indus, Sutlej, and Brahmaputra, flow south through the Himalayas (Harris, 2006). The ISM is closely connected with other major climate systems including the East Asian Monsoon (EAM) and the Western Pacific Monsoon (Salinger et al., 2014). Concerns over future dependability of ISM precipitation underscores the need to understand natural variability of the monsoon and respective climatic drivers, including the increasing role of anthropogenic influences. Natural variability combined with changing global climatic conditions paints a bleak picture of a monsoon system that will be less dependable with less precipitation which is devastating in a region that struggles with food deficits and inadequate potable water availability (Bollasina et al., 2011; Niyogi et al., 2010; Sinha et al., 2015; Tiwari and Joshi, 2012; Vrese et al., 2016). Projections of future monsoon rainfall are reliant on accurate and precise modeling of the integration of natural variability and climate change, based on both paleoclimate records and modern observations. Despite the importance of the ISM and a plethora of paleoclimate records, considerable knowledge gaps remain concerning how monsoon intensity has varied both temporally and spatially, indicating a need for more studies of climate in the region.

1.1 Indian Summer Monsoon & Regional Climate

The ISM, also referred to as the South Asian or summer Asian monsoon, is the dominant precipitation source for Southeastern Asia each summer (June-September). The monsoon is driven in part by the temperature gradient between sea surface temperatures (SSTs) and land, including the large arid land mass of the Tibetan Plateau (Molnar et al., 2010). Other recognized forces behind monsoon intensity include the migration of the Intertropical Convergence Zone (ITCZ), solar insolation, and larger climate systems, such as the El Niño-Southern Oscillation (Haug et al., 2001). The

modern extent of the monsoon is centered over the Indian subcontinent but expands north through the eastern Tibetan Plateau, west towards Pakistan and the tip of the Arabian Peninsula, and east in Bangladesh and western Myanmar. Isotopic signature of the monsoon is evident over a much larger area extending to the Arabian Peninsula (Fleitmann et al., 2003), Eastern China (Dykoski et al., 2005), and the Tanggula Mountains in central Tibet, China (Tian et al., 2001).

1.1.1 Seasonal Monsoon & Intra-Annual Variability

The onset of the monsoon season is dictated by temperature gradients between the Indian Ocean and the dry, arid Tibetan Plateau along with the seasonal migration of the Intertropical Convergence Zone (ITCZ) and the orographic effects of the mountainous terrain (Chen et al., 2014; Gadgil, 2003). The maximum northern position of the ITCZ is reached during the summer months, which corresponds with the onset of the monsoon rainfalls and the respective strength of the monsoon (Fleitmann et al., 2007). The elevation of the TP plays a significant role in the intensity of the seasonal monsoons (Harris, 2006; Wu et al., 2007). A low-pressure system pulls in warm, humid air from the Indian Ocean, producing intense precipitation of the southern slopes of the Himalayas with moderate rainfall further inland (Harris, 2006). Intra-annual variability of the monsoon consists of active and break periods in rainfall that are attributed to tropical convergence zones and intra-seasonal oscillations (Goswami and Mohan, 2001). Monsoon seasons can vary year to year in intensities, rainfall amounts, and in timing of the onset and the length of the monsoon season. Failures of the monsoon, characterized by drought conditions during the monsoon season, have been attributed to reduced wind strength and cooler temperatures (Cook et al., 2010).

Multiple drivers of these inter-annual changes in monsoon intensity have been identified through modern observations and supplemented with paleoclimate records. Ocean-atmosphere conditions in the Indian Ocean and tropical Pacific Ocean are considered to be key drivers of inter-annual variability in the ISM rainfall. Previous research indicates that the ENSO moderates the ISM by reducing the length of the rainy season resulting in decreased rainfall (Cook et al., 2010; Gadgil et al., 2004; Goswami and Xavier, 2005; Thompson, 2000). El Niño events have the greatest influence on the

ISM rainfall by cooling the air over the Indian subcontinent and weakening easterly trade winds along with increasing atmospheric subsidence and convection (Kumar et al., 2006; Yeh et al., 2009) and are associated with monsoon failures and drought conditions (Cook et al., 2010; Thompson, 2000); with La Nina conditions resulting in a stronger monsoon due to stronger easterly trade winds. The EQUINOO (Equatorial Indian Ocean Oscillation) when overlapping with ENSO conditions can also affect monsoon rainfall with positive (negative) phases being associated with stronger (weaker) monsoons (Surendran et al., 2015). Both the Indian Ocean Dipole (IOD) and the Pacific Ocean Dipole (POD) have a positive correlation with ISM rainfall, although research on how these climate forcings influence the monsoon on longer time-scales is still ongoing (Ashok et al., 2001).

The ITCZ, where winds and precipitation converge in a latitudinal zone, is another crucial driver of the summer monsoon (Fleitmann et al., 2007). The summer position of the ITCZ drives how far inland precipitation falls, with a more northerly trajectory linked to higher rainfall amounts. The winter position of the ITCZ, which reaches its southern-most position in January, drives a winter monsoon system. The winter monsoon has an inverse relationship with the summer monsoon, with heavier snowfalls in Eurasia correlating with decreased summer monsoon rainfall (Blanford, 1884; Walker, 1910), but analyses suggest that this relationship is most apparent in extreme anomalies rather than an annual trend (Bamzai and Shukla, 1999).

1.1.2 Historical Monsoon Variability

Decadal monsoon variability is affected by the same drivers of inter-annual variability: Indian and Pacific Ocean and atmosphere conditions. Modern records have shown a strengthening of the relationship between monsoon rainfall and the Indian Ocean post-1976 AD due to warming SSTs (Clark et al., 2000). The short instrumental record, however, prevents much analysis on longer time scales. As such there is a substantial need for understanding how the monsoon has varied on longer time scales using paleoclimate records. These paleoclimate records have identified long-term and abrupt changes to the monsoon in connection with the ITCZ, solar insolation, and ENSO

conditions (Bird et al., 2010; Cook et al., 2010; Dykoski et al., 2005; Fleitmann et al., 2007).

The short instrumental (1930s to present) and historical records in the ISM region necessitate the need for developing paleoclimate records from natural archives, such as lake sediments, to interpret long-term changes. Centennial and decadal-resolved records are particularly sparse in the ISM region (Bird et al., 2017; Bird et al., 2014), which limits the understanding of monsoon variability on shorter-time scales. Existing studies of the ISM have demonstrated long-term millennial changes in the ISM since the early Holocene where the monsoon was strongest, before transitioning to a weaker monsoon in the Middle Holocene (5-3 ka) that persists today (Chen et al., 2014; Djamali et al., 2010; Seki et al., 2009). However, the timing of the weakening of the monsoon is not consistent between records, which suggests that the timing of changes in ISM rainfall may be spatially-dependent. Higher-resolution records have demonstrated that even within periods described by long-term records as either strong or weak monsoons, there can be significant variability on shorter-time scales (Bird et al., 2014). Consideration of the ISM response to climate events is important as there has not been agreement between global responses to the MCA and LIA and the responses seen in the ISM region which may be critical in understanding how climate forcings differ in this region (Bird et al., 2017; Mann et al., 2009; Sinha et al., 2015).

Large-scale interpretations of regional climate are made possible with comparisons of paleoclimate records from a variety of deposits and environments using proxies or indicators of natural climate conditions. Paleoclimatology relies on proxies, or indicators, of past climate conditions that are preserved in natural archives including marine and freshwater sediments, ice caps, tree rings, and speleothems. Lakes are a critical, sensitive terrestrial archive for both within lake processes (*i.e.* water quality, lake level) and watershed environmental conditions (*i.e.* climate, land use). Lakes are well distributed across biomes and elevations and most have high sedimentation rates, making them sensitive to climate conditions on shorter-time scales and at higher spatial frequencies than most natural archives. Lake-specific sedimentation rates can provide information on varying time-scales, from seasonal to decadal. Sediments record information about conditions within the lake and the surrounding watershed with typical

proxies including geochemistry and isotopes, sedimentology, and biological fossils. The diverse proxies found in lake sediments can be used to interpret local, regional, and global climate-processes. Dating of these sediments makes it possible to interpret temporal changes in climate and compare records from other lakes and archives (Bird et al., 2017; Bird et al., 2014). In most lakes, sediments are continuously deposited, with rare hiatuses associated with extreme dry conditions (Fleitmann et al., 2003), and well preserved making them a useful archives of regional climate and watershed specific responses. In the Tibetan Plateau, lakes are a valuable archive for paleoclimate due to the high density of lakes in the region while other archives, such as tree rings, are less prevalent in the region.

Precipitation is not as well constrained as temperature in paleoclimate records, because it is less spatially homogenous than temperature, with precipitation levels varying significantly with location. Indicators of precipitation and other measures of the hydrological cycle, such as evaporation, are recorded in lake sediments through multiple proxies, including isotopes, biological indicators, and directly through physical evidence of changing lake levels. This project utilizes both ^{18}O and ^2H isotopes, with a focus on ^2H extracted from leaf-wax *n*-alkanes, to interpret hydrologic changes including precipitation and evaporation during the summer monsoon. The correlation between $\delta^2\text{H}$ and $\delta^{18}\text{O}$ reflects global and local meteorological water lines (GMWL and LMWL; Craig, 1961). Deuterium excess ($d = \delta^2\text{H} - 8 \times \delta^{18}\text{O}$) is a measure of the deviation between the expected linear relationship of $\delta^{18}\text{O}$ and $\delta^2\text{H}$ (GMWL: $\delta^2\text{H} = 8.0 \times \delta^{18}\text{O} + 10\%$), which varies spatially and reflects local fractionation processes (Dansgaard, 1964). Both $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values are impacted by temperature, elevation and amount effects, with amount effects playing the largest role in monsoon isotopic expression (Tian et al., 2003; Vuille et al. 2005).

Isotopic records combined with other sedimentological proxies are crucial for interpretations of how the ISM has varied throughout the Holocene. The ISM was strongest during the early Holocene, during a period known as the Holocene Climate Optimum (10.5-6.5 ka), but began to weaken during the middle Holocene (~5.2 ka; e.g., (Campo and Gasse, 1993; Chen et al., 2014; Djamali et al., 2010). In the paleoclimate record from Paru Co, a lake sampled in this study, maximum ISM rainfall in the study

region was between 10.1 – 5.2 ka, after which conditions became drier (Bird et al., 2014). The timing of this transition to a weaker monsoon differed between isotopic and sedimentological proxies, which suggests that monsoon isotopic signatures reflect regional synoptic conditions while the sedimentology reflects local watershed responses. The monsoon continued to weaken into the late Holocene, where two climate events occurred: the Medieval Climate Anomaly (MCA: 950-1250 AD), and the Little Ice Age (LIA: 1400-1700 AD; Mann et al., 2009). Existing records are not in agreement about how these climate events influenced monsoon precipitation. Some records found a moderate strengthening of the monsoon during the MCA, but no response to the LIA (Bird et al., 2017; Sinha et al., 2015).

1.2 Precipitation & Isotopes

Hydrogen and oxygen isotopes are useful for studying both relative volume and trajectories of precipitation across terrestrial landscapes and have been used in many studies of the Asian monsoons. Isotopic measurements of hydrogen ($\delta^2\text{H}$) and oxygen ($\delta^{18}\text{O}$) are strongly influenced by moisture source and climate, including temperature and the amount of precipitation (Gat, 1996; Tian et al. 2018). Modern isotopic observations have found that the ISM extends across the Indian subcontinent, west to the Brahmaputra Valley, and north towards the Tanggula Mountains, where both the tropical and temperate air masses converge and the northernmost extent of the summer ITCZ lies (Tian et al., 2001). Monsoon precipitation from the Indian Ocean and Indian subcontinent reaches the Tibetan Plateau in two primary directions: from the Bay of Bengal through the Brahmaputra Valley and across the subcontinent towards the Himalayan slopes, providing a significant orographic effect on northern India. Summer rainfall travels through the southeast corner of the plateau and is then redistributed to the north and west, reaching the central and western plateau through the Nyainqêntanglha Mountains. Mean annual precipitation in the Tibetan Plateau ranges from 172 to 650 mm with driest conditions in the western plateau and at higher altitudes (Tian et al., 2001; Tian et al., 2003).

Isotopic analyses of modern precipitation have generally found there is little variation between the global and local meteoric water lines during the monsoon,

reflecting a low evaporation signal (Breitenbach et al., 2010; Tian et al., 2001). Isotopic measurements of $\delta^{18}\text{O}$ and $\delta^2\text{H}$ in northeastern India near the Bay of Bengal during the monsoon range from 0.8 to -18.8 ‰ and 18.5 to -144.4 ‰, respectively (Breitenbach et al., 2010). Monsoon rainfall on the Tibetan Plateau has been found to have consistently lower $\delta^{18}\text{O}$ values between -5‰ to -20‰ (Tian et al., 2003). Winter precipitation, in contrast to summer monsoon rainfall, has been observed to be more enriched due to continental recycling and different moisture sources signal (Breitenbach et al., 2010; Tian et al., 2003). $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values are more affected by amount effects than temperature in the monsoon region in contrast to areas on the plateau that are dominated by continental precipitation sources (Thompson, 2000; Tian et al., 2003). Modeling of different forcings, suggest that temperature, transportation, and distillation processes (*i.e.*, rainout and depletion) all affect the isotopic signature of monsoon rainfall (Vuille et al., 2005).

New techniques have allowed for the measurement of hydrogen isotopes incorporated into organic biological compounds, such as lipids produced by terrestrial and aquatic vegetation, producing new isotopic proxies (Aichner et al., 2010; Eglington and Eglington, 2008; Polissar and D'Andrea, 2013; Sachse et al., 2012). These new proxies allow for isotopic measurements of precipitation in lake systems that do not have carbonate sediments which was not possible previously. With the southeastern Tibetan Plateau dominated by non-carbonate lakes, this project is utilizing terrestrial and aquatic leaf-wax *n*-alkanes to measure hydrogen isotopic variability in the ISM region. These results will be verified with carbonate $\delta^{18}\text{O}$ measurements where carbonate sediments are available. Both terrestrial and aquatic plants incorporate hydrogen atoms from their respective water sources and use them in the synthesis of lipids and other biological compounds. Studies have found that these organic biological compounds, including *n*-alkanes, alkanolic acids, and fatty acids, provide an indirect measurement of the isotopic composition of precipitation at the time of synthesis (Aichner et al., 2010; Feakins et al., 2016; Hou, 2008; Nichols, 2010).

Interpretations of these isotopic measurements should consider the influences of regional climate, local hydrology (*i.e.*, evaporation and condensation), and plant physiology (*i.e.*, photosynthetic pathways and water uptake) on isotopic fractionation

(Hou, 2008). Plant physiology significantly affects $\delta^2\text{H}_{\text{wax}}$ values and is reflective of the $\delta^2\text{H}$ of xylem water in plants, which is directly sourced from soil water (Feakins et al., 2016). $\delta^2\text{H}_{\text{wax}}$ has been demonstrated to follow the same spatial trends as $\delta^2\text{H}$ of precipitation and lake water, but is highly fractionated from those isotopic values (Hou, 2008). Site specific characteristics also influence $\delta^2\text{H}_{\text{wax}}$ including a negative correlation with elevation and continentality (Feakins et al., 2016). Consideration of both regional and site-specific influences on precipitation isotopes is necessary to make interpretations of how monsoon and other precipitation systems vary spatially and temporally.

Both $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values have been shown to decrease through the monsoon season which has been interpreted more as either a reflection of the source waters (Breitenbach et al., 2010) or an amount effect (Clark and Fritz, 1997; Datta et al., 1991; Kurita et al., 2009; Tian et al., 2003; Vuille et al., 2005; Zhang et al., 2006). The surface waters of the Bay of Bengal, the water source for summer rainfall, undergoes significant isotopic variation throughout the monsoon season due to large fluxes of river runoff (Breitenbach et al., 2010). The amount effect has been observed through an inverse relationship between annual precipitation accumulation and $\delta^{18}\text{O}$ values in both precipitation studies and ice core records (Thompson, 2000; Tian et al., 2003). Studies have found that the extent of the isotopic signatures of the monsoon has varied throughout the Holocene, reaching as far as the Near East (Djamali et al., 2010), the Arabian Peninsula (Fleitmann et al., 2003; Fleitmann et al., 2007) and caves in southern China (Dykoski et al., 2005; Maher, 2008). However, more records are needed to understand how isotopic measurements vary across different time scales (Thompson, 2000; Tian et al., 2003; Yao et al., 2000), as some paleoclimate records show that isotopic trends have varied significantly through the Holocene (Fleitmann et al., 2003; Zhang et al., 2008).

1.3 Modern Monsoon & Climate Change

Modern weather monitoring in the Tibetan Plateau (TP) began around the 1930s and, currently, there are 97 monitoring stations above 2,000 m and an additional 100 at lower altitudes (Liu et al., 2000). Analysis of modern temperature records have shown that most of the plateau has experienced significant warming since the 1950s, with the

eastern plateau warming slower than other regions (Gou et al., 2007; Liu et al., 2000; You et al., 2008). Calculated evapotranspiration (ET) in the region has decreased in all seasons between the 1960s and 2000 (Shenbin et al., 2006). During that same period (1961-2000), precipitation for the region increased, particularly for the eastern Tibet, but declined in western Tibet (Xu et al., 2008). The growing season has increased throughout the region with an associated decline in the number of days with frost or ice (You et al., 2008). Temperature reconstructions from ice cores and glaciers have also shown a recent warming trend (Thompson et al., 1989; Thompson et al., 1993; Yao et al., 1995). Warming conditions in the TP have been linked with human-induced changing climate (Anmin et al., 2006).

Recent warming on the plateau exceeds the average for the Northern Hemisphere, indicating that this region is particularly vulnerable to changing climate (Liu et al., 1998; Liu et al., 2000). Since the region contains abundant glaciers and permafrost, it is commonly referred to as *The Third Pole Environment* (Qui, 2008). Yet with warming temperatures, the Tibetan Plateau is already experiencing changing conditions, including glacial retreat, melting permafrost, and an altered hydrological cycle (Yang et al., 2011; Yao et al., 2007). Glacial retreat is widespread through the plateau (Tang et al., 1998; Yao et al., 2012) and is a significant concern as a water storage loss. Glacial retreat has been increasing since the 1960s when measurements first began and is connected to a roughly 5% increase in river discharge (Yao et al., 2007). In addition to glaciers, Tibet also has areas of discontinuous and sporadic permafrost. Permafrost melting has increased in relation to warmer soil temperatures connected to an overall warming region (Cheng and Wu, 2007). Soil temperatures are increasing at a faster rate than air temperatures, making the whole region more susceptible to changing climate (Zhao et al., 2004). Climate change has been recognized to have a greater impact at higher altitudes with alpine regions exhibiting greater sensitivity (Yao et al., 2000).

Reviews of meteorological observations of the monsoon system has shown that the monsoon has underwent significant changes throughout the 20th and early 21st centuries. Monsoon intensity has decreased since the mid-20th century although the total precipitation has increased slightly (Bollasina et al., 2011). Simultaneous with decreasing monsoon intensity, the monsoon season has also been shortening, with the monsoon onset

occurring later (Mondal et al., 2014). A hypothesis for weakening monsoon intensity is that increasing volumes of aerosols in the region are impacting monsoon intensity (Bollasina et al., 2011; Sinha et al., 2015). The anthropogenic aerosols in the region, referred to as Asian Dust, are linked to the burning of wood and fossil fuels due to intensive industrialization and population growth. Another consideration is the increased importance of sea surface temperatures (SSTs) in the Indian and Pacific Oceans, which corresponds to warmer SSTs post-1976 AD (Clark et al., 2000).

The future of the ISM is of great scientific interest and is particularly important in the context of the human communities in the region. The Tibetan Plateau has been inhabited for the past 15,000-20,000 years (Barton, 2016), with most communities dependent on subsistence agriculture and nomadic shepherding. Subsistence and nomadic agriculture are highly dependent on monsoon rainfall and its effects on the short growing season in the plateau, which will be substantially affected by monsoon variability. Models of future impacts of changing climate predict reduced rainfall, delayed onset and higher frequency of dry periods within the monsoon season (Ashfaq et al., 2009). Higher Indian Ocean temperatures are expected to produce more extreme storm events and unpredictability in the monsoon precipitation (Kumar et al., 2006). The future monsoon is also expected to be strongly impacted by anthropogenic processes, including agricultural intensification and aerosol emissions (Bollasina et al., 2011; Niyogi et al., 2010; Sinha et al., 2015; Vrese et al., 2016). With over 40% of the world's population reliant on this rainfall, the social and economic ramifications of dry periods are potentially devastating (Gadgil et al., 2004).

1.4 Geological Setting

The Tibetan Plateau (77°E to 105°E and 25°N to 40°N) encompasses the Tibetan Autonomous Region and the southern edge of Qinghai province in southwest China along with areas within Nepal and northern India. The plateau itself has a mean elevation greater than 5,000 m (ASL) and includes an area of approximately 2,500,000 km² (Harris, 2006; Liu et al., 2000). Commonly called the *Roof of the World*, the plateau is highly mountainous and has steep surficial relief. The plateau is bordered by the Inner Himalayan Range to the south, the Kunlun Range to the north, and Qilian Range to the

northeast. This region was formed through orogenic processes resulting from a continental collision (convergent boundary) between the Indo-Australian and Eurasian plates that began approximately 50 Mya (Yin and Harrison, 2000; Zhiseheng et al., 2001). Terrestrial and marine sediment analyses have shown that the Asian monsoons developed in phase with uplift of the plateau (Zhiseheng et al., 2001).

Modern dominant geomorphic processes revolve around glaciers, fluvial systems, and mass movements. The Tibetan Plateau is often referred to as the Third Pole Environment due to its high concentration of glaciers and ice caps (Xu et al., 2008). Glacial melt and snowmelt in the spring and early summer are a critical part of the region's hydroclimate by providing base flow to rivers (Yao et al., 2007). Fluvial systems in the region move a massive volume of sediment and dissolved materials with rivers from this region are responsible for over a quarter of all dissolved matter deposited to the oceans (Palmer and Edmond, 1992). These morphological processes may be impacted by future climate conditions, with reduced glaciation and more intense rainfall which will affect fluvial systems and mass movements.

1.5 Records of Holocene ISM Intensity

Existing Holocene climate records for the summer monsoon have been developed from ice cores, speleothems, and lake and bog sediments (Dykoski et al., 2005; Herzschuh et al., 2009; Liu et al., 1998; Mgler et al., 2008; Shao et al., 2010; Shi et al., 2001; Yanhong et al., 2006). Predicting how continued greenhouse gas emission induced warming will impact rainfall from the ISM requires high frequency resolved climate records. However, the majority of these proxies are at a low-resolution, often on centennial or millennial timescales, which can overlook climate variability on shorter time scales that are more relevant to human communities. Only three long-term records from the region were resolved at a decadal level: Mawmluh Cave (Berkelhammer et al., 2012), Tianmen Cave (Cai et al., 2012), and Nam Co (Zhu et al., 2008). An important consideration in the study of the ISM throughout the Holocene is how the monsoon rainfall and lake level has varied spatially. There is not a cohesive understanding of whether or not the monsoon extent has varied extensively during the Holocene and, if so,

what drives the spatial extent. That is why assessment of paleoclimate records in southeastern Tibet can provide more information on spatial trends.

Most studies of Holocene climate divide the period into the early (11 – 6.5 ka), middle (6.5 – 2.5 ka), and late (2.5 ka – present) Holocene for their interpretations, with most studies focusing on either the early or late Holocene. The early Holocene was characterized by a strong monsoon, with higher rainfall interpreted in lake, ice, and cave records (Campo and Gasse, 1993; Chen et al., 2014; Djamali et al., 2010; Seki et al., 2009). The Holocene Climate Optimum (10.5-6.5 ka) was a period marked with wet and warm conditions across South Asia, with a strong Indian summer and East Asian monsoon (Seki et al., 2009). The middle Holocene was more varied, with most studies agreeing that the monsoon started to weaken during this period (Campo and Gasse, 1993; Chen et al., 2014; Djamali et al., 2010). Many studies of forcings for the changing monsoon in the early and middle Holocene focus on changes in solar insolation and the migration of the ITCZ (Bird et al., 2014; Cai et al., 2012; Chen et al., 2014; Fleitmann et al., 2007). Decreasing levels of solar insolation over the Holocene coincides with millennial scale decreases in monsoon intensity (Bird et al., 2014; Cai et al., 2012; Fleitmann et al., 2007). One record from the Chinese Loess Plateau suggests a connection between Bond Events in the North Atlantic Oscillation (NAO) and dry conditions on the plateau (Porter and Weijian, 2006), but there is not widespread agreement on this hypothesis between records. The ITCZ is also considered to play a role in the strength of the monsoon, with studies suggesting that a northern ITCZ coincided with stronger monsoon rainfalls in the early Holocene (Chen et al., 2014; Fleitmann et al., 2007). The ITCZ migrated further south during the middle Holocene at the same time as declines in solar insolation, however it is difficult to distinguish which driver played a more significant role in the weakening of the monsoon during this time period.

Specific records vary on when the monsoon weakened during the middle Holocene with dates ranging from 5 – 3 ka (Bird et al., 2014; Cai et al., 2012; Herzschuh et al., 2006; Hong et al., 2003; Xuefeng et al., 2006; Yanhong et al., 2006; Zhu et al., 2008). There are two conflicting hypotheses about how the transition between a strong and weak monsoon occurred. The first hypothesis is that there was an abrupt decrease in monsoon rainfall that occurred sometime between 5 – 4.5 ka (Morrill et al., 2003). The

second, more prominent, hypothesis is that the monsoon weakened gradually simultaneous with decreasing solar insolation (Dykoski et al., 2005; Fleitmann et al., 2003; Gupta et al., 2003; Ivanochko et al., 2005; Wang et al., 2005). Hiatuses in some records, such as the speleothems in Mawmluh Cave around ~3.8 ka and Qunf Cave around ~2.7 ka, suggest dry conditions with insufficient moisture to continue carbonate deposition (Berkelhammer et al., 2012; Fleitmann et al., 2003). The timing of the transition to a drier climate and weaker monsoon varies between sites which may also reflect a spatial influence on the distribution of ISM moisture. One study in the near-east demonstrated that the decline of the monsoon during the middle Holocene led to major forest cover changes, which might have indicated a reduction in the influence of the monsoon on that area (Djamali et al., 2010).

The late Holocene ISM has generally been described as weak, due to lower solar insolation and a more southerly ITCZ (Chen et al., 2014). High-resolution records for the ISM during the late Holocene are less prevalent than those for the early Holocene, due to insufficient material with many hiatuses present in paleoclimate record (Berkelhammer et al., 2012; Fleitmann et al., 2003). A key driver for variability throughout the Holocene, particularly the late Holocene, is the connection between Indian-Pacific Ocean SSTs and the ENSO (El Niño Southern Oscillation) system. El Niño conditions reduce ISM strength and La Niña conditions result in stronger monsoons, relationships that have been established in other published records (Cook et al., 2010; Thompson, 2000). The Dasoupu ice core made strong correlations between drought conditions, indicated by increased dust and chloride concentrations, and El Niño events in the late Holocene (1790-1796 AD, 1876-1877 AD; Thompson, 2000). In another study, Cook et al. (2010) identified large droughts, megadroughts, from tree rings with several events correlating with El Niños (1790-1796 AD, 1876-1877 AD, 1918-1919 AD). The effects of the ENSO system are moderated by the distribution of Indian and Pacific Ocean SSTs (Cook et al., 2010). The Medieval Climate Anomaly (MCA) and the Little Ice Age (LIA) were two major climate events during the late Holocene that have been found in numerous Northern Hemisphere paleoclimate records, with the MCA being a period of anomalous warmth and increased precipitation and the LIA being a period of colder temperatures and reduced precipitation (Mann et al., 2009). Records from the ISM region have not

shown the same relationships between precipitation and the MCA and LIA as other Northern Hemisphere records, emphasizing a need to further understand how these events influenced monsoon intensity (Bird et al., 2017; Sinha et al., 2006; Sinha et al., 2015; Zhang et al., 2008). The modern late Holocene was also characterized by the industrialization-induced warming period that is exhibited in paleoclimate records including ice cores and lake sediments (Thompson, 2000; Wang et al., 2011). Some records have also shown that the 20th century warming period is also connected to a weaker monsoon, with lower lake levels and more frequent droughts (Cook et al., 2010; Wang et al., 2011).

The MCA was marked by warmer temperatures (positive temperature anomalies) with persistent La Niña conditions in the tropical Pacific (Mann et al., 2009), however some modeling has contradicted this observation (González-Rouco et al., 2011). Warming was estimated to have exceeded early-20th century warming across the Northern Hemisphere including the North Atlantic, the Eurasian Arctic, Northern Africa, and North America (Goosse et al., 2012; Mann et al., 2009). Theoretical modeling of the temperature increases in MCA have suggested an integrated forcing with weak increases in solar radiation producing altered atmospheric-ocean circulations including northern migration of the Gulf Stream and Kuroshio currents (Goosse et al., 2012; Servonnat et al., 2010). The LIA is characterized by cooling across the Northern Hemisphere, but isolated warming in some areas in North America and Eurasia (Mann et al., 2009). Theorized forcing for the LIA are reduced solar radiation and increased atmospheric volcanic aerosols (Servonnat et al., 2010; Yan et al., 2015). How the Asian monsoons responded to these events is not fully understood. Select records suggest that the MCA may have resulted in a slight increase in ISM precipitation, which may be attributed to the La Niña state in the Pacific, and a weak response to the LIA (Bird et al., 2017; Sinha et al., 2015), which may have coincided with a southern migration and contraction of the ITCZ (Yan et al., 2015).

Many paleoclimate records of the ISM emphasize millennial trends in hydroclimate, but finer resolution records have demonstrated that there are centennial and decadal-scale variabilities that are superimposed onto the long-term trends. Sedimentology at Paru Co, for example, demonstrated that during the strong monsoon in

the early Holocene, there were five distinct high and low lake stands (Bird et al., 2014). These events, described on centennial time scales, are an important indication that broader, millennial trends miss finer variability in monsoon rainfall. Other records have also demonstrated that greater rainfall variability exists through the Holocene, but is superimposed on the long-term trends (Fleitmann et al., 2007). Finer resolution records are also crucial in understanding how the hydroclimate system responds to specific events, such as the MCA and LIA (Bird et al., 2017).

1.6 Research Questions & Site Selection

In this dissertation, I address some of this uncertainty of Holocene ISM expression by providing new, high-resolution lake sediment records from the southern Tibetan Plateau (TP), where precipitation is predominately from the ISM (Tian et al., 2001). Three small lakes were sampled along an east-west transect across the southeastern to south-central TP: Galang Co, Nir'Pa Co, and Cuobu. All three lakes have relatively small watersheds that showed no evidence of recent glaciation or human-disturbance, reducing non-climatic watershed influences on the sediment records. The plant communities at each site are dependent on monsoon precipitation during their growing season, allowing for the use of leaf-wax *n*-alkane proxies for assessing hydrogen isotopes. Both Cuobu and Nir'Pa Co are high-elevation lakes that were selected for understanding higher, temporal variability in local and synoptic hydroclimate variability in the south-central and southeastern TP respectively. Galang Co is a relatively low-elevation lake in a heavily vegetated watershed, selected to determine whether ISM expression is consistent between high and low elevation sites.

Sediment cores from these three lakes are used to address the primary objectives of this project which include understanding 1) long-term ISM variability throughout the Holocene and what time-scales are appropriate for understanding hydroclimate variability, 2) timing of transitions between stronger and weaker monsoon conditions during the middle Holocene, and 3) how the ISM has responded to specific climatic events, such as the MCA and LIA. Each record consists of proxies that demonstrate changes in precipitation, lake levels, and watershed conditions throughout the Holocene (11.7 ka – present). These proxies were selected to address the primary objectives of this

project, as described earlier, and to test my hypotheses. With current climate models predicting an increase in droughts and delayed onset of the monsoon season, the reliability of the ISM for water during the growing season in this region is under threat. This project improves future climate modeling of the region by providing multiple decadal-resolved records of lake levels and precipitation across the eastern plateau during the past 10,000 years. Expanding the knowledge of the ISM region's climate history is crucial for understanding how the monsoon may vary in the future and how those variabilities might impact the human communities dependent on that system.

2. RECONSTRUCTING LATE HOLOCENE HYDROCLIMATE VARIABILITY USING SHORT AND LONG CHAIN *n*-ALKANE HYDROGEN ISOTOPES, NIR'PA CO TIBET

2.1 Introduction

The Indian summer monsoon (ISM) is the primary precipitation source for the Tibetan Plateau and the adjacent region, which is referred to as the Third Pole Environment (Qui, 2008). Paleoclimate records from this region generally agree that ISM precipitation declined throughout the Holocene after having reached a broad maximum during the early Holocene (11.7 – 7 ka; Berkelhammer et al., 2012; Bird et al., 2014). Between 7 and 5 ka, the ISM weakened, reaching a minimum during the late Holocene around 3.5 ka. The late Holocene (3.5 ka to modern) has been described as an arid period relative to the early Holocene, with reduced monsoon precipitation and hiatuses in some archives (*i.e.*, Berkelhammer et al., 2012; Fleitmann et al., 2003). The Medieval Climate Anomaly (MCA: 950-1250 AD) and the Little Ice Age (LIA: 1275-1700 AD) are two events during the late Holocene that produced temperature and precipitation anomalies across the northern hemisphere with the onset of these events attributed to volcanic aerosols, sea ice temperature feedbacks, and solar radiation (González-Rouco et al., 2011; Mann et al., 2009; Miller et al., 2012; Polissar et al., 2006). As a result, the spatiotemporal expression of late Holocene climate events, including the MCA and the LIA, are not as well represented in the paleoclimate record as other early and middle Holocene events. There are questions about whether the MCA or LIA had an impact on ISM precipitation and the extent of that impact, due to limited records from this period on the Tibetan Plateau.

Previous results from Nir'Pa Co, a small alpine lake on the southeastern Tibetan Plateau, suggested that hydroclimate in this region and the ISM more broadly was driven by Pacific sea surface temperatures (SSTs), with warmer air temperatures on the Tibetan Plateau corresponding to warmer western Pacific SSTs and greater ISM intensity, with most of the late Holocene characterized by pronounced drought between 2.3 and 1.3 ka, evidenced by high sand content indicating shallow lake conditions, which is bracketed by wetter intervals (Bird et al., 2017). Higher silt and sand during the MCA and LIA

respectively both suggest that the monsoon was relatively stronger and weaker during these events, but is superimposed on a broader trend towards a stronger monsoon from 1.2 to 0.2 ka. The sedimentology record suggests that the MCA and LIA were minor hydroclimatic events compared to the drought between 2.3 and 1.3 ka (Bird et al., 2017). This period was characterized with a decrease in lithics and an increase in sand suggesting shallow lake conditions and reduce monsoon rainfall. These drought conditions corresponded with colder temperatures (Herzschuh et al., 2006) and drier conditions at other sites in the Tibetan Plateau (Gu et al., 1993) and was attributed to an El-Niño state in the Pacific.

Climate forcings that contributed to the weaker monsoon during the late Holocene has also been attributed to the southward migration of the intertropical convergence zone (ITCZ), reduced solar radiation, and a shift towards El Niño-like conditions characterized by anomalous warming in the eastern Pacific and cooling in the western Pacific (Bird et al., 2017; Fleitmann et al., 2003). The MCA and LIA events, which were driven by volcanic aerosols, sea ice temperature feedbacks, and solar radiation (González-Rouco et al., 2011; Mann et al., 2009; Miller et al., 2012; Polissar et al., 2006), produced La Niña conditions (anti-phase of the El Niño) during the MCA while El Niño conditions characterized the LIA (Mann et al., 2009). An El Niño-state in the Pacific has also been attributed to a weaker monsoon from 2.3 and 1.3 ka when drought conditions were evident at Nir'Pa Co (Bird et al., 2017). Yet questions remain about ISM fluctuations during the late Holocene and the role of larger climate drivers of monsoon expression. One point of contention is when the strong relationship between the ISM and the El Niño-Southern Oscillation (ENSO) was established, with some records suggesting that the relationship between ISM precipitation and Indo-Pacific SSTs developed around the middle of the Holocene when the ITCZ shifted southwards (Bird et al., 2017; Bird et al., 2014). Another question is how ENSO conditions were expressed during the MCA and LIA and what role this played on the strength of ISM precipitation on the Tibetan Plateau. New hydroclimate records spanning the late Holocene from the Tibetan Plateau are needed to address these questions.

To assess ISM precipitation variability during the late Holocene, this study uses a multi-proxy approach that integrates hydrogen isotopes ($\delta^2\text{H}$) of long- and short-chain *n*-

alkanes from sedimentary aquatic and terrestrial and leaf waxes with previously published geochemical and sedimentological data from Nir'pa Co (Bird et al., 2014; Mügler et al., 2008; Polissar and D'Andrea, 2014). The short-chain *n*-alkanes were specifically used to investigate the isotopic variability of Nir'pa Co's lake water, which incorporates isotopic variability associated with ISM precipitation and the local precipitation:evaporation (P:E) balance, while long-chain *n*-alkane $\delta^2\text{H}$ variability was used to investigate synoptic scale ISM variability. By subtracting long- and short-chain *n*-alkane $\delta^2\text{H}$ values from each other, I additionally derived an independent record of local P/E variability. When integrated with the previously published geochemical and sedimentological results, these new biogeochemical data provide a more robust and comprehensive perspective of late Holocene ISM variability at local and synoptic scales and their interrelationships. The 3.4 ka record of the isotopic composition of short vs. long-chain *n*-alkanes from Nir'Pa Co is compared with paleoclimate archives from around the Third Pole Environment and the broader Pacific region. This study addresses 1) how the monsoon at Nir'Pa Co is expressed across the late Holocene with an emphasis on the response to the weak monsoon from 2.2 to 1.2 ka as well as the MCA and LIA, 2) whether the isotopic expression of the monsoon at Nir'Pa Co agrees with the sedimentology record, and 3) whether monsoon expression is driven by SSTs in the Indo-Pacific.

2.2 Study Area

Nir'pa Co is a small (0.1 km²), high elevation (4775 m a.s.l) alpine lake in the Nyainqêntanglha Mountains on southeastern Tibet (29.734° N, 92.386° E; Fig. 2.1). The lake has an ephemeral inlet on the northwestern shore with a small outflow on the southwestern shore. The lake's bathymetry consists of a deep central basin (max. water depth = 15 m) and shallow shelves (water depth = ~1 m) on the northwestern and southeastern edges of the lake near the inlet and outlet, respectively (Fig. 2.3). With an ephemeral outlet, the lake is highly sensitive to evaporation as a closed lake system. The lake vegetation includes macrophytes, such as algae and grasses, in the shallow shelf while the deep basin is unvegetated. The surrounding watershed is sparsely vegetated

with C3 and C4 small flowering plants and mosses during the summer season, but vegetation is dormant during the cold winters.

Nir'pa Co's watershed consists of steep mountains (5120 m a.s.l.) and a narrow (1.5 km), glacially carved u-shaped valley (4815 a.s.l.) that extends for over 5 km (Fig. 2.2). The lake is positioned at the southeastern end of the valley and is dammed by a terminal moraine. The regional geomorphology is dominated by past glacial activity, but glaciers have been absent for the duration of the Holocene (Li et al., 1991). The regional climate is dominated by the ISM which accounts for 96% of total annual precipitation (total annual precipitation: 514 mm; May-September precipitation: 495 mm) with moderate summers and cold winters (mean annual temperature: 9.6°C; monthly average temperature range: 0.6-17.3°C; Fig. 2.4). Ice cover is present during the winter months (December-February), preventing evaporation during this time. Precipitation and temperature data were collected from the Lhasa station (Lhasa: 3650 m a.s.l.; 120 km from Nir'Pa Co; 29.667° N, 91.133° E).

2.3 Methods

2.3.1 Sample Collection

A 90-cm surface core (A-11) was collected in May 2011 from the deepest part of the Nir'pa Co's basin (water depth = 17.5 m) using an Aquatic Research hammer corer. Two additional cores, A-15 and B-15, were collected in June 2015 using a piston surface corer. Representative samples of the terrestrial and aquatic vegetation communities were collected from within the lake and around its immediate watershed in June 2015.

2.3.2 Chronology

An age model for Nir'Pa Co A-11 was produced using a combination of ^{210}Pb , ^{137}Cs , and ^{14}C (Bird et al., 2017). Ten samples from the top portion of the core underwent direct gamma counting to measure ^{210}Pb , ^{214}Pb , and ^{137}Cs (Appleby and Oldfield, 1978). Two radiocarbon (^{14}C) dates were measured using accelerator mass spectrometry (AMS) at the Keck AMS Laboratory, University of California Irvine. Both samples consisted of charcoal fragments that were collected from a wet sieve at 63 μm , manually cleaned, and

chemically pretreated with an acid-base-acid wash using 1 N HCl and 1 N NaOH (Olsson, 1986). Radiocarbon dates were calibrated using the IntCal 0.914c data set with the CALIB 6.0 program (Stuiver and Reimer, 1993). All dates for this core are reported as median probability age and 2σ error in calendar years before present (BP; 0 = 1950 CE).

2.3.3 Lipid Extraction & δ^2H Analysis

Forty-two samples from the A-11 core were analyzed for *n*-alkane hydrogen (δ^2H) isotopes at the Lamont-Doherty Earth Observatory Organic Geochemistry Lab, Columbia University. Sediment samples were dried and homogenized before undergoing total lipid extraction (TLE) using a 9:1 dichloromethane to methanol solvent on a Dionex ASE-350. The TLE then underwent separation on a silica column (70-230 mesh, 60A) with hexane solvent to isolate the aliphatic fraction. The aliphatic fraction underwent silver nitrate column (10 % AgNO₃) chromatography separation with hexane as a solvent to isolate *n*-alkanes.

The distributions and concentrations of *n*-alkanes in each sample were determined using an Agilent Technologies 7890A gas chromatography mass spectrometer (GCMS). Short chain *n*-alkanes (nC23) are produced by both submerged and emergent aquatic macrophytes (Ficken et al., 2000; Seki et al., 2009) while long chain *n*-alkanes (nC29 and nC31) are produced by terrestrial vascular plants (Meyers, 2003). Intermediate *n*-alkanes (nC25 and nC27) can reflect a mixture of aquatic and terrestrial vegetation sources, but are also produced by aquatic (nC25) and terrestrial vascular (nC27) vegetation.

Several indices were used to assess the sources and distributions of *n*-alkanes. The average chain length (ACL) and carbon preference index (CPI) were calculated to assess changes in the distribution of *n*-alkanes (Diefendorf et al., 2015; Marzi et al., 1993). Higher ACL and CPI values indicate terrestrial vegetation inputs in lake sediments while lower values are indicative of aquatic vegetation (Mügler et al., 2008). The aquatic vegetation index (P_{aq}) was calculated to assess the concentration of low and mid-chain *n*-alkanes (aquatic inputs) versus longer chains (terrestrial inputs; Ficken et al., 2000). Higher P_{aq} index values indicate greater aquatic productivity (Ficken et al., 2000; Seki et al., 2009).

$$ACL = \frac{25[C25] + 27[C27] + 29[C29] + 31[C31] + 33[C33] + 35[C35] + 37[C37]}{[C25] + [C27] + [C29] + [C31] + [C33] + [C35] + [C37]}$$

$$CPI = \frac{([C23] + [C25] + [C27] + [C29] + [C31] + [C33] + [C35]) + ([C25] + [C27] + [C29] + [C31] + [C33] + [C35] + [C37])}{2 \times ([C24] + [C26] + [C28] + [C30] + [C32] + [C34] + [C36])}$$

$$P_{aq} = \frac{[C23] + [C25]}{[C23] + [C25] + [C29] + [C31]}$$

δ^2H *n*-alkane isotopic measurements were made using a Thermo Scientific Trace Ultra GCMS (GC column: 30m, 0.25mm, 14.2 psi, 60°C) and Delta V Plus IRMS (isotope ratio mass spectrometer). Both an isotopic (Mix A7) and a lab standard were run with replicate sample injections. Reported values are reported in standard delta notation with per mil (‰) units relative to the VSMOW (Vienna Standard Mean Ocean Water) scale after being corrected using MATLAB. Isotopic variability between replicate measurements ranged between 2.9-3.4% (Polissar and D'Andrea, 2014).

2.3.4 Effective Moisture

nC23 is derived from aquatic plants, which incorporate hydrogen atoms directly from lake water, thereby reflecting its isotopic composition, but with some degree of offset (Mügler et al., 2008; Seki et al., 2009). nC31 is derived from terrestrial plants, which incorporate hydrogen atoms from soil water that is derived directly from precipitation (Xia et al., 2008). The δ^2H for nC31 therefore reflects variations in the isotopic composition of precipitation, while δ^2H for nC23 reflects changes in lake water isotopic compositions that incorporate evaporation and changes in lake volume as well as changes in the isotopic composition of the precipitation that fed the lake. The large difference in hydrogen isotope values between terrestrial (nC31) and aquatic vegetation (nC23) is driven by the enrichment of δ^2H in lake water due to high evaporation of the system (Guenther et al., 2013) and fractionation during biosynthesis, with aquatic plants exhibiting a large, negative fractionation (Mügler et al., 2008). The subtraction of

normalized isotopic measurements of nC31 from nC23 hence removes isotopic variability in the lake water $\delta^2\text{H}$ attributable to changes in precipitation $\delta^2\text{H}$ and those factors that influence it (moisture source, distance from source, temperature, etc.), thereby providing an estimation the ratio of precipitation to evaporation (Mügler et al., 2008). Higher $\Delta\delta^2\text{H}_{\text{C23-C31}}$ values indicate greater evaporation relative to precipitation and vice versa for lower values.

2.4 Results

2.4.1 Sedimentology

The sedimentology of the A-11 core consisted of homogenous, fine grained sediments that were reddish-brown with slightly darker bands around 30 and 60 cm. Organic fragments including charcoal and grass were dispersed throughout the core (Bird et al., 2017).

2.4.2 Short vs. Long-chain *n*-alkanes

Concentrations of *n*-alkanes varied significantly between the modern sediments and the early part of the record (~3.4 ka; Fig. 2.5 and Table 2.1). The full dataset is in Appendix 1, Table A 1.1. Throughout the record, short chain leaf waxes were more abundant (nC23-nC25: $1.07 - 1.36 \times 10^8$ ng/100 μl) than long chain alkanes in the record (nC27-nC31: $9.04 \times 10^7 - 1.0 \times 10^8$ ng/100 μl). Noticeably *n*-alkanes were higher during the MCA (950-1250 AD) and decreased during the LIA (1275-1700 AD).

ACL values ranged between 27.9 and 28.66 while CPI values ranged from 4.05 to 4.55 over the last 3.4 ka (Fig. 2.5F-G). Both the ACL and CPI were consistently low between 3.4-2.25 ka (average: ACL: 28.2, CPI: 4.2) and increased from 2.25-1.25 ka (average: ACL: 28.3, CPI: 4.3). ACL decreased sharply at the beginning of the LIA (~610 BP; ACL: 27.9).

P_{aq} ranged between 0.41 and 0.53, which shows that the contribution of aquatic vegetation was high for most of the sediment record, but peaked at the beginning of the LIA (~610 BP; $P_{\text{aq}} = 0.53$; Fig. 2.5G). Aquatic vegetation steadily decreased after that peak and has remained lower in the modern sediments (300 yrs. BP to present).

2.4.3 Leaf Wax δ^2H

Hydrogen isotopic measurements (δ^2H) for C23, C25, C27, C29, and C31 *n*-alkanes extracted from the Nir'Pa Co sediments ranged from -287‰ to -237‰ for the last 3.4 ka (Fig. 2.6: A-E). δ^2H shows high variability throughout the record for all chain lengths. All *n*-alkanes were higher at the beginning of the record (nC23-nC31: -270.5‰ to -247.2‰) and subsequently decreased by 6 to 8.6‰. δ^2H remained lower until ~2750 BP when δ^2H for all *n*-alkanes increased with nC23 and nC25 showing the greatest enrichment (5.3 and 6.7‰, respectively). Isotope values plateaued until they decreased again during the MCA with the lowest values occurring at the beginning of the LIA (620 BP: -280 to -253‰). The isotopic responses during the LIA were lower. Modern *n*-alkane sediment δ^2H values are highest, with values ranging between -267.4 to -243.5‰ (300 yrs. BP to present).

2.4.4 Effective Moisture

$\Delta\delta^2H_{C23-C31}$ represents the hydrogen isotopic difference between nC23 and nC31 *n*-alkanes (Fig. 2.6F). $\Delta\delta^2H_{C23-C31}$ ranged between -7.7 to 5.6‰ with high variability throughout the record. $\Delta\delta^2H_{C23-C31}$ was positive between 3 and 1.2 ka and in the modern part of the record. $\Delta\delta^2H_{C23-C31}$ was negative in the earliest part of the record from 3.3 and 3 ka and between 1 ka and 250 BP, which includes the MCA and LIA, with the lowest $\Delta\delta^2H_{C23-C31}$ values at 600 BP (-7.7‰).

2.5 Discussion

2.5.1 Localized Hydroclimate at Nir'Pa Co

The previously published geochemical and sedimentological results from Nir'Pa Co suggested relatively wet conditions between 3.4 and 2.4 ka, an abrupt transition into and out of a pronounced dry interval at 2.4 and 1.3 ka, respectively, and a return to relatively wet conditions from 1.2 ka to the present (Bird et al., 2017). The new δ^2H results from Nir'Pa Co support this interpretation, but provide important additional information about the nature of local hydroclimate conditions and its relationship with

synoptic-scale ISM variability during the late Holocene. Here, I use the $\Delta\delta^2\text{H}_{\text{C}_{23}-\text{C}_{31}}$ time series as an indicator of local hydroclimate conditions at Nir'Pa Co and compare it with established lithics and percent sand time series from the lake. The Nir'Pa Co record indicates that the ISM varied significantly over the late Holocene, transitioning between strong and weak phases that influenced the local hydroclimate as inferred by $\delta^2\text{H}$ measurements and $\Delta\delta^2\text{H}_{\text{C}_{23}-\text{C}_{31}}$. Local hydroclimate conditions are indicated by short-chain *n*-alkanes and $\Delta\delta^2\text{H}_{\text{C}_{23}-\text{C}_{31}}$ while synoptic hydroclimate is inferred by long-chain *n*-alkanes. At Nir'Pa Co $\delta^2\text{H}_{\text{C}_{23}}$, which incorporates both monsoon intensity and evaporation from lake water, is used to infer local hydroclimate while $\Delta\delta^2\text{H}_{\text{C}_{23}-\text{C}_{31}}$ represents the hydrologic balance between precipitation and evaporation. The $\delta^2\text{H}$ record is compared with the sedimentology record at Nir'Pa Co (Bird et al., 2017), with high sand content inferred as low lake level, attributed to the increased proximity of the core site to the littoral zone of the lake. While the modern monsoon is relatively weaker than at any other point in the Holocene, with enriched $\delta^2\text{H}_{\text{C}_{23}}$ and high terrestrial vegetation inputs, there are two earlier periods that show significant variability in the local hydroclimate record at Nir'Pa Co: the LIA and 2.4 to 1.3 ka, with the former characterized as a relatively strong monsoon and the latter as weak monsoon (Fig. 2.7).

The event between 2.4 to 1.3 ka showed an extended significant impact on hydroclimate at Nir'Pa Co. During this period, $\Delta\delta^2\text{H}_{\text{C}_{23}-\text{C}_{31}}$ values are high which indicates higher evaporation at Nir'Pa Co. Low lake level conditions during this weak monsoon period are indicated by high terrestrial vegetation inputs, exhibited with more abundant longer-chain *n*-alkanes and low P_{aq} values. Observations for increased %sand during this period supports a low lake level interpretation and support the conclusion of arid conditions at Nir'Pa Co from 2.4 to 1.3 ka. Comparing the lake level signal of percent sand to the $\delta^2\text{H}_{\text{C}_{23}}$ and results, it is apparent that while the response of $\delta^2\text{H}$ to changes in monsoon intensity is gradual the transition from low to high sand content are more abrupt. The sudden influx of sand could be an indication of the lake reaching a threshold where the stand is low enough to expose the shelf on the northeastern edge of the lake, with a minimum decrease of one meter in water level to expose the shelf.

$\Delta\delta^2\text{H}_{\text{C}_{23}-\text{C}_{31}}$ decreases across the MCA suggesting that evaporation was declining across this period. In contrast, the LIA (675-250 BP) showed significant variability in

$\delta^2\text{H}_{\text{C}23}$ with the lowest values at the beginning of the LIA and an increase at the end of the event. Evaporation was low throughout the LIA as indicated by $\Delta\delta^2\text{H}_{\text{C}23-\text{C}31}$. More abundant short-chain *n*-alkanes and high P_{aq} values indicate that aquatic vegetation input has been high at Nir'Pa Co for most of the late Holocene, but there is a significant increase during the LIA which corresponds with the decrease in $\delta^2\text{H}_{\text{C}23}$ (Fig. 2.7D). The positive correlation between aquatic productivity and strong monsoon conditions could be interpreted as a lake level signal with a deeper lake producing a greater area for submerged and emergent plant habitat. Comparing with the sand record at Nir'Pa Co (Fig. 2.7E; Bird et al., 2017), the MCA and LIA can be interpreted as a period with highly fluctuating lake levels, with deeper lake conditions towards the beginning of the LIA. The combined lake level and isotopic record suggest that there was little impact of the MCA on local hydroclimate at Nir'Pa Co, while the LIA had a larger, but more variable impact.

2.5.2 Local and Synoptic Hydroclimate Relationships at Nir'Pa Co

Long-chain *n*-alkane $\delta^2\text{H}$ closely reflects the isotopic expression of precipitation (Xia et al., 2008) and, therefore, is used to assess synoptic or regional scale expression of the ISM. Monsoon intensities inferred by $\delta^2\text{H}_{\text{C}31}$ exhibit the same broad trends as local hydroclimate $\Delta\delta^2\text{H}_{\text{C}23-\text{C}31}$ with wetter conditions at Nir'Pa Co from 3.4 to 2.4 ka and 1.3 ka to present. Synoptic ISM variability at Nir'Pa Co agrees with the weak monsoon interpretation from 2.4 to 1.3 ka and is also evident in the local hydroclimate proxies with high sand and terrestrial vegetation. The LIA is evident with a strong monsoon at the beginning of the event around 610 BP in conjunction with low $\Delta\delta^2\text{H}_{\text{C}23-\text{C}31}$ and high aquatic vegetation. There is minimal evidence of any impact of the MCA on monsoon intensity on a synoptic scale, although the increase in silt and lithics suggests a local hydroclimate response with deeper lake conditions. The combination of local and synoptic hydroclimate records at Nir'Pa Co indicate that the drought event from 2.4 to 1.3 ka was consistently expressed at local and synoptic scales, while the LIA showed a small increase in monsoon strength while the MCA was not clearly expressed.

2.5.3 Regional Paleoclimate

Late Holocene records of ISM variability on the Tibetan Plateau are generally coherent with the interpretation of hydroclimate variability at Nir'Pa Co. For example, local hydroclimate at Paru Co, located only 7.5 km northwest of Nir'Pa Co, shows a deeper lake from 3.4 to 2.5 ka and 1.3 ka to present, with an intermittent shallow lake from 2.5 ka to 1.3 ka which corresponds with lake level interpretations at Nir'Pa Co (Fig. 2.7F-G; Bird et al., 2014). Lake level at Paru Co is inferred by percent sand and principal component analysis of grain size data variability. Higher lake levels at Paru Co between 3.3 – 2.5 ka and 1.3 ka to present with an intermittent period of lower lake levels are consistent with a deeper lake at Nir'Pa Co from 3.4 to 2.4 ka and 1.3 ka to present and a shallow lake from 2.4 to 1.3 ka. Another lake on the Tibetan Plateau, Seling Co, 370 km northwest of NPC, shows high $\delta^{18}\text{O}$ between 2.2 and 1.2 ka, suggesting increased evaporation during this time that is consistent with the low stands at NPC and Paru Co (Gasse et al., 1996; Gu et al., 1993). Like NPC and Paru Co, the Seling Co $\delta^{18}\text{O}$ record also shows no significant departures during either the MCA or LIA, suggesting these events minimally impacted local hydroclimate.

ISM precipitation on the plateau corresponds to shifts between cooler and warmer air temperatures as evidenced by the Lake Zigetang pollen index record from the central plateau, east of Seling Co (Herzschuh et al., 2006). The late Holocene was characterized by a more alpine steppe biome with greater dominance of Cyperaceae and similar cold hardy vegetation. This pattern was emphasized with a significant cooling between 2 and 1.5 ka that reflects the aridity evident in other plateau records. There is a paucity of high-resolution temperature reconstructions from the Tibetan Plateau making it difficult to assess evaporation rates especially during the winter months. The Lake Zigetang pollen record corresponds to summer climate and can't provide information about how winter climate has varied throughout the late Holocene, with warmer winter temperatures decreasing ice cover that could increase evaporation in the lake.

Synoptic variability in the ISM is indicated by leaf-wax *n*-alkane isotopic variability at Paru Co (Fig. 2.7G). The broad trend of long-chain *n*-alkane $\delta^2\text{H}$ (C27 and C29) of Paru Co shows that synoptic monsoon response was weak between 2.3 and 1.2 ka and relatively strong during the MCA which coincides with the higher-resolution

$\delta^2\text{H}_{\text{C31}}$ record at Nir'Pa Co. Synoptic record of ISM precipitation in the Dunde ice core in the north-central Tibetan Plateau, shows a more consistent strong monsoon during the MCA and LIA inferred by lower $\delta^{18}\text{O}$ (Thompson et al., 2006). Comparing the synoptic and local hydroclimate records across the Tibetan Plateau there is general agreement between local and synoptic proxies with the exception of the stronger monsoon intensity during the MCA and LIA in the Dunde ice core. A possible explanation for this difference is that the Dunde ice core record is not influenced by any biosynthesis fractionation compared to the leaf-wax *n*-alkane records at Nir'Pa Co and Paru Co.

2.5.4 Forcing Mechanisms

Evaluating the mechanisms that drove hydroclimate variability on the plateau require the consideration of paleoclimate records from beyond the Tibetan Plateau (Fig. 2.8). The Dongge speleothem record in southeastern China is influenced mainly by the East Asian Monsoon, but has also been theorized to be affected by the ISM due to its location on the margins between the two systems (Fig. 2.8C; Dykoski et al., 2005). Noticeably, Dongge Cave shows a much drier late Holocene with wetter conditions during the modern with less variability than at Nir'Pa Co.

Qunf Cave in Southern Oman is an ISM record that is located at the furthest western extent of the monsoon and the northern point of the ITCZ (Fig. 2.8D; Fleitmann et al., 2003; Fleitmann et al., 2007). The isotopic record of precipitation is less variable and drier than at Nir'Pa Co in the early part of the late Holocene with a steady decline in precipitation across the Holocene which is inferred as the southward migration of the ITCZ. Precipitation increases around the MCA and LIA before declining again. The long hiatus at Qunf Cave between 2.7 and 1.4 ka is attributed to a significant decline in the monsoon that halted deposition and agrees with reduced ISM precipitation on the plateau. A *Globigerina bulloides* foraminifera record (Fig. 2.8E) from the Arabian Sea suggest increased (decreased) upwelling in conjunction with higher (Battarbee et al., 2001) monsoon precipitation on land (Gupta et al., 2003). Upwelling is inferred in that record as an increase in wind strength from the monsoon, with upwelling remaining low for most of the late Holocene, decreasing and remaining stagnant between 2.2 to 1 ka before increasing during the MCA.

Marine and lake sediment records from the Pacific and Indian Oceans inferred to represent El Niño-Southern Oscillation variability provide a possible explanation of how sea surface temperatures and wind patterns drive monsoon rainfall across the plateau. The sand record at El Junco Crater Lake, in the Galapagos Islands, has been argued to indicate higher frequency of El Niño events (Fig. 2.8F; Conroy et al., 2008). Deeper lake level at El Junco defined by high sand influxes and lower C to N ratios occurred from 2 to 1.5 ka when the Asian monsoon was at its weakest points. A transition to El Niño conditions during the late Holocene also coincided with a southward migration of the ITCZ as evidenced in Qunf Cave (Fleitmann et al., 2003) and the Cariaco Basin (Haug et al., 2001). Laguna Pallcacocha sedimentology record from the Ecuadorian Andes exhibits higher frequency of El Niño conditions during the mid-late Holocene, but does not show the same extreme response or temporal duration of these events as El Junco likely influenced by its inland and higher elevation site (Fig. 2.8G; Moy et al., 2002).

Eastern Pacific SSTs were estimated from the ratio of Mg to Ca from *Globigerina bulloides* foraminifera collected in a sediment core near the Baja Peninsula of Mexico (Fig. 2.8H; Marchitto et al., 2010). Warmer temperatures in the eastern Pacific are indicative of an El Niño state while cooler temperatures indicate La Niña conditions, resulting in higher and lower rainfall respectively on the western coast of North and South America. The sparse record does suggest warmer conditions between 1.5 to 1 ka, when the Asian monsoon was weaker. SSTs in the tropical western Pacific are interpreted as cooler (warmer) temperatures indicate El Niño (La Niña) conditions (Fig. 2.8I; Stott et al., 2004). Surface waters were cooler for most of the late Holocene, with warmer temperatures during the MCA suggesting La Niña conditions during this period. Indian Ocean SSTs also indicate warmer temperatures between 2 and 1.2 ka and cooler temperatures during the MCA and LIA indicating La Niña and El Niño conditions respectively (Fig. 2.8J; Tiwari et al., 2006). The increased prevalence of El Niño conditions during the late Holocene has been attributed to declining solar insolation and warmer ocean upwelling resulting in decreased ISM precipitation intensity (Marchitto et al., 2010).

2.6 Conclusions

The leaf wax record at Nir'Pa Co demonstrates that there has been high variability in the ISM throughout the late Holocene with a pronounced weakening of the monsoon between 2.4 to 1.3 ka and a minimal hydroclimate response to the LIA. The modern monsoon is at its weakest point in the Holocene evidenced by high terrestrial vegetation inputs, enriched $\delta^2\text{H}$, and greater evaporation at Nir'Pa Co. Comparisons between the isotopic record and grain size records at Nir'Pa Co show that the lake level response to the ISM is more abrupt, suggesting a threshold for lake level changes. Weaker monsoon intensity at Nir'Pa Co corresponds with an El Niño-state in the Pacific and Indian Oceans as well as warmer temperatures on the plateau while stronger monsoon conditions reflect a La Niña-state and cooler temperatures on the plateau. Comparisons with paleoclimate records within the ISM extent and broader teleconnections shows that the period between 2.4 to 1.3 ka with weaker monsoon intensity was influenced by El Niño conditions in the Pacific.

2.7 Tables

Table 2.1: Average concentration of *n*-alkanes in Nir'Pa Co sediments

TIME PERIOD	NC23	NC25	NC27	NC29	NC31
249 TO -67 BP	1.09x10 ⁸	1.39 x10 ⁸	9.69E+07	1.09 x10 ⁸	1.28 x10 ⁸
675 TO 250 BP	7.42 x10 ⁷	9.52 x10 ⁷	5.67 x10 ⁷	5.33 x10 ⁷	5.75 x10 ⁷
1000 TO 700 BP	1.18 x10 ⁸	1.58 x10 ⁸	1.01 x10 ⁸	1.02 x10 ⁸	1.12 x10 ⁸

Figure 2.1. The location of Nir'Pa Co (NPC; red circle) in reference to other regional climate records. Lake sediment archives including El Junico (EJ), Lake Zigetang (LZ), Pallcacocha (PA), Paru Co (PC), and Selin Co (SC) are represented with circles. Cave records from Dongge Cave (DC) and Qunf Cave (QC) are represented with squares. The Dunde ice core (DU) is represented with a triangle. Marine sediment cores from the Arabian Sea (AS), Eastern Pacific (EP), and the Western Pacific (WP) are represented with stars. The Lhasa weather station (LH) is marked with an open circle.

Figure 2.2. The Nir'Pa Co watershed and surrounding area with the lake at the end of a 5 km long glacially carved valley.

Figure 2.3. Bathymetric map of Nir'Pa Co with 2 m contour intervals. The respective core sites for A-11, A-15, and B-15 are designated with red circles. Location of the inlet and outlet to the lake are marked with the location of the moraine that terminates the watershed.

Figure 2.4. Monthly total precipitation (mm \pm s.d.) and average temperature (°C \pm s.d.) at the Lhasa weather station. The monsoon season (May-September) is marked with a shaded gray background.

Figure 2.5. Total concentration of extracted long-chain C23 – C31 *n*-alkanes from sediment samples (ng/100 µL; A- E). Terrestrial lipid distribution as indicated with the Carbon Preference Index (CPI; F), Average Chain Length (ACL; G), and the aquatic vegetation index (P_{aq} , H). Vertical black lines indicate the average value. The LIA and MCA time periods are marked with light blue and dark blue backgrounds (indicating wetter conditions) while 2250-1250 BP is marked with red background (indicating drier conditions).

Figure 2.6. Leaf wax $\delta^2\text{H}$ (‰ VSMOW) $\pm 1 \sigma$ s.e.m. for C23 (A), C25 (B), C27 (C), C29 (D), and C31 *n*-alkanes. $\Delta\delta_{\text{C23-C31}}$ shows the variation between isotopic values between *n*C23 and *n*C31 (F). A more positive $\Delta\delta$ value indicates higher evaporation while a more negative $\Delta\delta$ indicates lower evaporation. Vertical black lines indicate average values. The LIA and MCA time periods are marked with light blue and dark blue backgrounds (indicating wetter conditions) while 2250-1250 BP is marked with red background (indicating drier conditions).

Figure 2.7. Nir'Pa Co $\delta^2\text{H}$ nC23 (‰; A), $\delta^2\text{H}$ nC31 (‰; B), $\Delta\delta^{23}\text{C}_{23-23}\text{C}_{31}$ (‰; C), P_{aq} (D), and sand grain size (%; E). Compared with local climate records from Paru Co sand (%; F), principal components (G), $\delta^2\text{H}$ for nC27 and nC29 (‰; H), Seling Co $\delta^{18}\text{O}$ (‰; I), Lake Zigetang pollen index (J), and Dunde ice core $\delta^{18}\text{O}$ (‰; K). Vertical black lines indicate the average value for each proxy. The LIA and MCA time periods are marked with light blue and dark blue backgrounds (indicating wetter conditions) while 2250-1250 BP is marked with red background (indicating drier conditions).

Figure 2.8. Comparison of Nir'Pa Co $\delta^2\text{H nC}_{31}$ (‰; A) and $\Delta\delta_{\text{C}_{23}\text{-C}_{31}}$ (B) data with regional monsoon records and global forcing. Regional monsoon records include Dongge Cave $\delta^{18}\text{O}$ (‰; C), Qunf Cave $\delta^{18}\text{O}$ (‰; D), and Arabian Sea marine core $\delta^{18}\text{O}$ (‰; E). Pacific records include El Junico sand grain size (%; F), Pallacocha red sediment color intensity (G), Eastern (H) and Western Pacific (I) and Indian Ocean (J) SSTs (Sea Surface Temperatures °C). Vertical black lines indicate the average value for each proxy. The LIA and MCA time periods are marked with light blue and dark blue backgrounds (indicating wetter conditions) while 2250-1250 BP is marked with red background (indicating drier conditions).

3. HOLOCENE INDIAN SUMMER MONSOON INTENSITY OVER THE SOUTH-CENTRAL TIBETAN PLATEAU INFERRED FROM SEDIMENTOLOGY AND LEAF-WAX *n*-ALKANE HYDROGEN ISOTOPES

3.1 Introduction

The Indian summer monsoon (ISM) is the primary climatic system that delivers moisture to the Tibetan Plateau, accounting for more than 90% of annual precipitation for eastern and central Tibet (Tian et al., 2007). Assessing long-term and abrupt ISM variability on the Tibetan Plateau is critical because of this region's role as a water tower for much of South Asia; several of the largest rivers in South Asia have headwaters on the plateau that are reliant on stored monsoonal precipitation in the form of groundwater and glacial melt for baseflow. Model simulations suggest that these water resources are threatened by climate change (Kumar et al., 2006; Li et al., 2017; Sharmila et al., 2015), with projections of warmer air and sea surface temperatures, decreasing land-sea temperature gradients, a driving mechanism behind ocean-atmosphere circulation and the ISM. Understanding how these ocean-atmosphere circulation changes will impact the ISM is crucial, as the reliance on seasonal monsoon precipitation will increase as glaciers disappear from the landscape (Qui, 2008). Because instrumental records for the region are short (1930s to present) and spatially underrepresented at high elevations and remote regions of the Third Pole (Tian et al., 2007), paleoclimate records are essential for determining the long-term relationships between hydrologic variability and local and global climate drivers.

Given its importance, there has been considerable effort expended to reconstruct Holocene ISM variability in recent decades. The majority of research indicates that ISM precipitation reached a maximum during the early Holocene from 11.7 – 7 ka before a decline in intensity between 7.5 and 5 ka, with evidence of an earlier decline in local monsoon precipitation and intensity (*e.g.* lake levels and erosion indicators) before synoptic scale changes reflected by isotopic records in some records (Berkelhammer et al., 2012; Bird et al., 2014; Dykoski et al., 2005; Fleitmann et al., 2003; Gupta et al., 2003). The expression of the weakened monsoon varies both spatially and temporally, with evidence that the monsoon expanded in the early Holocene reaching as far as

northern Iran to the west (Djamali et al., 2010) and southeastern China to the east, contracting during the middle Holocene as a result of weakened monsoon winds and precipitation (Gupta et al., 2003; Magny and Haas, 2004). The middle Holocene weakening of the ISM was driven by declining boreal summer insolation in the Northern Hemisphere (NH), which peaked around 11 ka and began to gradual decline after 8 ka (Berger and Loutre, 1991; Fleitmann et al., 2003; Wu et al., 2018). Reduction in solar insolation resulted in a southerly shift in the Intertropical Convergence Zone (Fleitmann et al., 2003; Haug et al., 2001), weakened ISM winds near the Arabian Peninsula (Gupta et al., 2003), cooler temperatures in the NH (Marcott et al., 2013) and the Tibetan Plateau (Herzschuh et al., 2009; Herzschuh et al., 2006), and a shift to El Niño-like conditions in the Pacific (Conroy et al., 2008; Marchitto et al., 2010; Moy et al., 2002). High frequency paleoclimate records from the Tibetan Plateau indicate that superimposed on these millennial scale changes in ISM are more frequent shifts between wet and drought conditions during the early Holocene (Bird et al., 2014). This study seeks to identify how high-frequency Holocene ISM variability was expressed in the south-central Tibetan Plateau, near the westernmost extent of monsoon precipitation on the Plateau, and investigate how relative precipitation and lake level proxies respond to local and global climate drivers.

To this end, a high-resolution, multi-proxy lacustrine paleoclimate record from Cuobu, a small alpine lake located in the Gangdise Mountains on the southern Tibetan Plateau (Fig. 1). Local-scale hydroclimate at the lake and watershed level was investigated/reconstructed using sedimentology, sediment geochemistry including $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ isotopes and x-ray fluorescence (XRF), total organic matter and carbonate, and short-chain *n*-alkane hydrogen ($\delta^2\text{H}$) isotopes. Synoptic-scale ISM intensity was investigated using long-chain *n*-alkane $\delta^2\text{H}$. Isotopic difference between long-chain and short-chain *n*-alkane $\delta^2\text{H}$ were additionally used to estimate the ratio of local precipitation:evaporation (P:E) as an indicator of local effective moisture. The Cuobu record in conjunction with other sites on the Tibetan Plateau and from the broader ISM region is used to assess: 1) Holocene ISM variability near the westernmost extent of the ISM on the Tibetan Plateau, 2) distinguish the timing and differences between how local and synoptic hydroclimate proxies respond to changes in monsoon intensity, especially

during the middle Holocene, and 3) how high-frequency hydroclimate variability responds to local and global drivers of the ISM.

3.2 Study Area: Cuobu

Cuobu is a small (1.1 km²) high elevation (4734 m a.s.l.) alpine lake located on the southern Tibetan Plateau in the Gangdise Mountains (Fig. 3.1; 29.55813° N, 87.02519° E). The bathymetry of the lake is largely shallow with a deep northern basin that reaches a maximum water depth of 5.1 m. The lake's littoral zone is heavily vegetated with submerged and emergent macrophytes and algae. The watershed is sparsely vegetated with a few species of ferns, flowers, and mosses. The water chemistry of the lake was slightly basic (pH=8.54) with moderate conductivity (137 mS/m) and alkalinity (36 mEq/L).

The regional geology consists of Pleistocene andesite bedrock (Choubert et al., 1983) with fluvial and glacial features. The watershed for Cuobu (8.4 km²) has been dominated by past glacial activity with the lake and its watershed resulting from the intersection of two valley glaciers (Fig. 3.2A). The watershed is flanked by steep mountain ranges to the north and southwest that reach maximum elevations of 5110 m a.s.l., while the eastern and southeastern edge of the watershed is flanked by a moraine (4750 m a.s.l.), which separates the lake from a river channel, referred to here as the Cuobu River (Fig. 3.2B). The lake is situated at the eastern edge of the watershed within a wide and long (2.5 km by 3.3 km) valley and is dammed by a long terminal moraine (2.2 km).

Cuobu's main tributary is an ephemeral stream that enters the lake on its northwestern corner (Fig. 3.1). Two secondary tributaries include a small stream positioned on the western edge of the lake and an ephemeral stream on Cuobu's eastern shore. This ephemeral secondary tributary is an overflow point of Cuobu River to the east of Cuobu's watershed, which is situated approximately 20 m higher in elevation than modern lake level, separated by a medial moraine (Fig. 3.2C). The geomorphic features associated with the overflow tributary (*e.g.*, vegetation growing within the channel, limited incision) suggest that overflow events are infrequent under current climatic conditions, but may have been more frequent at times in the past when ISM precipitation

was greater and river height increased sufficiently to reactive the channel. The wider channel that surrounds the modern channel incision suggests that this river sustained greater waterflow than the current channel can support. Outflow from Cuobu occurs via an outlet on the southern edge of the lake, however, there is little surface geomorphic evidence for sustained surface flow from the outlet. Instead, it appears that today groundwater seepage reaches the surface approximately 200 m downslope from the outlet, at which point it forms a permanent surface stream that eventually flows into the Dogxung Zangbo (River), a tributary to the Yarlung Tsangpo River, which has carved a steep valley through the area.

Data from the Xigaze weather station, (located ~180 km south the lake at 3837 m a.s.l.; 29.25° N, 88.883° E) indicates that the regional climate is relatively dry, with an annual total of 367 mm of precipitation (1988-2018; Fig. 3.3), compared with the northeastern (*i.e.*, Mischke, 2008) and southeastern Tibetan Plateau (Bird et al., 2017; Bird et al., 2014). Approximately 99% of this annual precipitation occurs during the monsoon season (June-September: 363 mm), with peak precipitation in July and August. This is later in the season than eastern sites along the plateau, indicating that it takes longer for monsoon precipitation to reach the southcentral region as the monsoon system originates in the southeast of the plateau near the Nyainqêntanglha Mountains. Water isotopes indicate that precipitation is greater than evaporation (mean $\delta^{18}\text{O} = -16.6\text{‰}$; mean $\delta^2\text{H} = -138.0\text{‰}$). Mean temperatures are cool (mean annual temperature = 7.1°C, mean monthly temperatures = -2.5 – 15.4 °C), with ice cover during boreal winter months preventing evaporation during this time (Dec-Feb: mean temperature = -1.73°C, total precipitation: 0.2 mm).

3.3 Methods

3.3.1 Sample Collection

Sediment cores, surface sediments, water, and vegetation samples were retrieved from Cuobu and its watershed in June 2017 (Fig. 1). Two surface cores, A-17 (core length = 69 cm, water depth = 5.05 m) and B-17 (core length = 85 cm, water depth = 4.3 m), were retrieved using a modified piston corer. Three longer sediment cores were

collected using a modified Livingstone piston corer (Livingstone, 1955; Wright, 1967). Each 1-meter-long drive was overlapped by 30 to 50 cm to ensure complete stratigraphic recovery. The C-17 core consisted of 9 drives (water depth = 4.3 m; 728 cm total recovery). The D-17 core was collected at a water depth of 4.4 m and consisted of 5 drives for a total recovery of 371 cm. A third core collected nearby E-17 consisted of 7 drives for a total recovery of 357 cm (water depth = 4.6 m). A composite of the B-17 surface and D-17 Livingstone cores was made based on magnetic susceptibility with a total core length of 431 cm.

A transect of 14 surface sediment samples was collected across the northern side of the lake using an Ekman grab sampler to characterize the modern distribution of sediment characteristics, including all of the down-core sediment proxies, across the lake basin and their relationship with water depth and proximity to shore. Two soil samples were collected from southeast shore of the lake. Samples of aquatic and terrestrial vegetation within and surrounding the lake were additionally collected. A water sample was collected for isotopic analysis. Water chemistry, including temperature, pH, alkalinity, and conductivity was measured on site at 1-meter depth intervals using a Hydrolab MS5. Sediment, vegetation, and water samples were subsequently stored and analyzed at the Paleoclimatology and Sedimentology Laboratory at Indiana University-Purdue University Indianapolis (IUPUI).

3.3.2 Sediment Dating

Sediment ^{210}Pb , ^{214}Pb , and ^{137}Cs was measured by direct gamma counting of 21 dry, homogenized samples from the upper 41 cm of the B-15 surface core at the University of Pittsburgh. The ^{210}Pb age model was produced using the constant rate of supply (CRS) model (Appleby and Oldfield, 1978). Radiocarbon (^{14}C) dates of bulk sediment samples from the F-17 core (n=10) were measured with accelerator mass spectrometry at the Keck AMS Facility, University of California Irvine. Bulk sediment samples were dried and treated with 1 N HCl (KCCAMS, 2011; Olsson, 1986). An age model combining radiocarbon, ^{210}Pb , ^{214}Pb , and ^{137}Cs dates was established using the program Bacon (Blaauw and Christen, 2011). Dates used in this age model are reported in calendar years before present (0 ka; 0 ka = 1950 of the common era).

3.3.3 Initial Core Description

Surface and Livingstone cores were split, described, and imaged using a GeoTex Multi-Sensor Core Logger at IUPUI's (Indiana University-Purdue University, Indianapolis) Paleoclimatology and Sedimentology Laboratory. Volumetric samples (1 cm³) were taken at 1 cm intervals for each core and drive respectively for bulk density and loss-on-ignition analysis. Wet samples were weighed, dried for 24 hours at 60 °C and reweighed to calculate dry bulk density (ρ_{dry} ; g/cm⁻³) and water content (%). Each sample was combusted 550 °C and 1000 °C for four hours and two hours, respectively, and weighed after each combustion to measure percent total organic matter (%TOM) and total carbonate (%TC; Heiri et al., 2001). Surface and Livingstone cores were subsampled at 1 cm and 0.5 cm resolutions respectively for further analysis.

Magnetic susceptibility is a measure of magnetic minerals in sediments, and is used to understand the deposition of lithics in lake sediments, with increased MS associated with higher influxes of terrestrial material to the lake during either wetter or drier conditions (Dearing, 1994; Thompson et al., 1975). Under wetter conditions the increase in MS is attributed to a greater volume of eroded terrestrial materials contributed to the lake; while drier conditions result in the concentration of terrestrial materials with lower lake levels winnowing these materials to the center of the lake. Conflicting scenarios for MS require an interpretation in conjunction with other proxies. MS was measured down-core at 0.5 cm intervals on the GeoTex Multi-Sensor Core Logger at IUPUI's Paleoclimatology and Sedimentology Laboratory.

3.3.4 Lithics & Grain Size

Distributions of sediment grain sizes were measured at 1 cm intervals across the B-17 and D-17 composite core. Grain size distributions of the surface sediments and soil samples were also measured. A portion of wet sediment (~1 g) was dried and weighed before soaking in 30% hydrogen peroxide (H₂O₂) for 24 hours. The sample was then treated with 5 aliquots of 20 mL of H₂O₂ at 70 °C to remove organic matter. Biogenic silica was removed by treating samples for 6 hours at 60 °C with 20 mL of 1 N sodium hydroxide (NaOH). Carbonates were removed from samples with greater than 3% TC as determined by LOI by treating samples with aliquots of 10 ml of hydrochloric acid (HCl)

for at least 1 hr or until there was no visible reaction. Samples were rinsed with DI water, freeze dried, and weighed to estimate %lithics. Sample preparation methods were modified from (Gray et al., 2010). Each sample was then treated with 2.5% sodium metaphosphate and sonicated. Each sample was run on a Malvern Mastersizer 2000 at IUPUI with final values the average of three measurements. Results were binned into 49 diameter size fractions between 0.2 and 2000 μm .

Grain size analysis is used to understand the influxes of sediments to the core site, but like MS, their interpretation needs to be considered within the context of other proxies. For instance, increases in grain size can indicate either lower lake levels, with the winnowing of coarse grains toward the deeper portions of the lake during low stands (Bird et al., 2017; Conroy et al., 2008; Dearing, 1997; Digerfeldt, 1986; Shuman et al., 2001; Shuman et al., 2009) or an increase in high-energy runoff and delivery of coarse terrestrial sediment to the lake during wet climatic conditions (*e.g.*, Conroy et al., 2008). In contrast, finer sediments can indicate either deeper lake levels during wetter climatic conditions (*i.e.*, increased distance between the core site and the sediment source) or a reduction in the energy of terrestrial runoff during drier conditions.

3.3.5 X-ray Florescence (XRF) Geochemistry

Scanning XRF geochemistry was measured at 0.5 cm resolution down the length of the B-17 surface core and D-17 Livingstone core drives. Measurements were made using an ITRAX XRF Core Scanner at the Large Lakes Observatory, University of Minnesota Duluth (Croudace et al., 2006) for select elements (Al – Ur) and are reported in counts per second (cps). A Cr source tube (30 kV, 55 mA) was used with a 15 second dwell time and 10 mm resolution. Peak optimization was made using Qspec 8.6.0 software.

3.3.6 Elemental Abundances & Isotopic Composition of Organic Carbon & Total Nitrogen

Measurements of total organic carbon (TOC), total nitrogen (TN), $\delta^{13}\text{C}$, and $\delta^{15}\text{N}$ were made at the Large Lakes Observatory, University of Minnesota Duluth. Sediment samples were measured at a 2 cm resolution for the composite B-17 and D-17 core.

Samples with less than 5% total carbonate as determined by LOI were homogenized and weighed (~4 mg) into tin capsules. Samples with greater than 5% total carbonate were homogenized and weighed (~12 mg) into silver capsules. The samples were injected with 50 μ l DI water and placed in a desiccator with an open beaker of 12M HCl. Samples were acidified overnight and air-dried to remove HCl before being placed in tin capsules.

Measurements were made with a Thermo Finnigan Delta Plus XP isotope ratio mass spectrometer (IRMS) fitted with a ConFlo III device and a Costech 4010 elemental combustion system at the Large Lakes Observatory, University of Minnesota Duluth. Samples were run against a series of standards including acetanilide, B-2153, B-2159, USGS41, and caffeine (standards from the National Institute of Standards and Technology). Values are reported in delta notation as the per mil (‰) deviation from Vienna Pee Dee Belemnite (VPDB) for $\delta^{13}\text{C}$ and air for $\delta^{15}\text{N}$. The coefficient of variation standards ranged between 1.4-3.8‰ for N and 0.5-2.5‰ for C while isotopic precision was 0.04-0.13‰ and 0.06-0.2‰ for $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$.

The ratio of total organic carbon to total nitrogen (C:N) reflects shifts in organic matter sources in lacustrine systems, with values under 10 indicating aquatic derived organic matter and values above 15 indicating terrestrial organic matter (Meyers, 1999). The isotopic composition of organic carbon ($\delta^{13}\text{C}_{\text{org}}$) is affected by photosynthetic pathways, with C_3 land plants and algae being isotopically similar (range: -30 to -25‰), depending on lake water CO_2 , while C_4 plants are more enriched (range: -14 to -10‰; Meyers, 1999). The isotopic composition of total nitrogen ($\delta^{15}\text{N}$) is also affected by productivity source, but must be considered in conjunction with other productivity proxies due to its complex nature as it also impacted by other processes, such as nitrogen cycling within the water column (Meyers and Lallier-Vergès, 1999). Higher $\delta^{15}\text{N}$ is often correlated with terrestrial productivity and a higher C:N ratio (Thornton and McManus, 1994).

3.3.7 Lipid Extractions & $\delta^2\text{H}$ Isotopes

Thirty-four samples were collected from the composite core for long-chain *n*-alkane extraction and hydrogen isotopic measurements ($\delta^2\text{H}$) at the Lamont-Doherty Earth Observatory, Columbia University. Lipids were extracted from homogenized

sediments with a 9:1 dichloromethane and methanol solvent on a Dionex Accelerated Solvent Extractor (ASE-350). The aliphatic fraction was isolated using hexane solvent across a silica gel column (70-230 mesh, 60A). Ketone and polar fractions were isolated subsequently using dichloromethane and methanol. The *n*-alkanes were purified with a second separation across a silver nitrate column (10% AgNO₃) with hexane solvent. *n*-alkane distribution and concentration was determined using an Agilent Technologies 7890A gas chromatography mass spectrometer (GCMS). Leaf wax $\delta^2\text{H}$ isotopic measurements were made on the extracted *n*-alkanes using a combined GCMS-IRMS (Thermo Scientific Trace GC Ultra GCMS and Delta V Plus IRMS; GC column: 30m, 0.25mm, 14.2psi, 60°C). A mixture of long-chain *n*-alkanes (Mix A7) and a reference sample were both used as standards. Values are reported in delta notation as the per mil (‰) deviation from VSMOW (Vienna Standard Mean Ocean Water). Sample isotopic values were corrected using MATLAB with uncertainties ranging between 3.2% and 4.2% (1 σ s.e.m.; (Polissar and D'Andrea, 2014).

Average chain length (ACL) quantifies whether short or long-chain *n*-alkanes are more abundant (Diefendorf et al., 2015; Mügler et al., 2008), while the carbon preference index (CPI) represents the ratio of odd to even carbon atoms in *n*-alkanes (Marzi et al., 1993). Higher values for both the ACL and CPI are indicative of more terrestrial organic matter in the lake, which suggests either increased productivity in the watershed and/or increased delivery of terrestrial organic matter to the lake.

$$\text{ACL} = \frac{25[\text{C25}] + 27[\text{C27}] + 29[\text{C29}] + 31[\text{C31}] + 33[\text{C33}] + 35[\text{C35}] + 37[\text{C37}]}{[\text{C25}] + [\text{C27}] + [\text{C29}] + [\text{C31}] + [\text{C33}] + [\text{C35}] + [\text{C37}]}$$

$$\text{CPI} = \frac{([\text{C23}] + [\text{C25}] + [\text{C27}] + [\text{C29}] + [\text{C31}] + [\text{C33}] + [\text{C35}]) + ([\text{C25}] + [\text{C27}] + [\text{C29}] + [\text{C31}] + [\text{C33}] + [\text{C35}] + [\text{C37}])}{2 \times ([\text{C24}] + [\text{C26}] + [\text{C28}] + [\text{C30}] + [\text{C32}] + [\text{C34}] + [\text{C36}])}$$

In contrast to the ACL and CPI, the aquatic vegetation index (P_{aq}) quantifies the abundance of short-chain *n*-alkanes in the sediments, with higher values indicating increased aquatic vegetation productivity (Ficken et al., 2000; Seki et al., 2009).

$$P_{aq} = \frac{[C23] + [C25]}{[C23] + [C25] + [C29] + [C31]}$$

3.3.8 Effective Moisture Estimation

Because the $\delta^2\text{H}$ of *n*-alkanes produced by aquatic vegetation (e.g., $\delta^2\text{H}_{\text{C}_{23}}$) reflect the $\delta^2\text{H}$ of lake water, it integrates isotopic variability related to both changes in ISM precipitation and lake volume changes as a result of evaporation. The later isotopic effects can be isolated by subtracting precipitation isotopic variability, captured by long-chain *n*-alkanes ($\delta^2\text{H}_{\text{C}_{31}}$), from aquatic isotopic variability ($\delta^2\text{H}_{\text{C}_{23}}$). The resulting so-called delta-delta index ($\Delta\delta^2\text{H}_{\text{C}_{23}-\text{C}_{31}}$) provides a semi-quantitative estimate of the ratio of precipitation to evaporation (P:E) where higher $\Delta\delta^2\text{H}_{\text{C}_{23}-\text{C}_{31}}$ values indicate a reduction in lake volume from greater evaporation relative to precipitation (i.e., lower effective moisture) whereas lower $\Delta\delta^2\text{H}_{\text{C}_{23}-\text{C}_{31}}$ values reflect an increase in effective moisture and lakes volumes as a result of reduced evaporation relative to precipitation (Aichner et al., 2010; Mügler et al., 2008; Seki et al., 2009).

3.4 Results

3.4.1 Core Description

The lithology of the composite core was characterized by massive units of light brown, fine grained sediments with small fragments of aquatic grasses throughout the core.

3.4.2 Age Model

Excess ^{210}Pb was highest in the top 2.5 cm (0.19-0.20 Bq/g) of the B-17 core and reached background levels at 22.5 cm (Table 3.1; Fig. 3.4). Only three samples had measurable ^{137}Cs at 2.5, 16.5, and 18.5 cm. Ten radiocarbon dates from bulk sediments were measured from the E-17 and D-17 core. Dates were calibrated using IntCal 13.0 (Reimer et al., 2013). The oldest radiocarbon date was 7910 ± 20 cal yr BP. Comparison between the ^{210}Pb and ^{14}C dates from the same depths at the top of the E-17 surface core

showed a carbon reservoir effect of 930 years, which was subtracted from all radiocarbon dates in the age model. The age model shows continuous deposition at the lake, with no hiatuses, and spans the past 8.34 ka (Fig. 3.5). Full age results for Cuobu are in Appendix 1, Table A 2.1.

3.4.3 Elemental Abundances & Isotopic Composition of Organic Carbon & Total Nitrogen

Total organic matter (%TOM) was lowest in the early Holocene from 8.3 – 5 ka, averaging 42.2% (Fig. 3.6A). %TOM gradually increased from 5 – 2 ka by 8.5%, then subsequently decreased from 2 ka to present (35.9%; Fig. 3.6A). Total carbonate (%TC) was low for most of the record with a mean of 5.6% (range: >0.01 – 41.2%), with elevated TC from 2.9 – 33.3% from 2.6 – 2.1 ka (Fig. 3.6B).

The ratio of total organic carbon to total nitrogen (C:N) averaged 9.3 across the Cuobu record (range: 6.1 – 12.2), with high C:N from 7.3 to 2.3 ka (range: 9.5-12.2) and lower C:N for the late Holocene (range: 6.1 – 9.2; Fig. 3.6E). At Cuobu, $\delta^{13}\text{C}_{\text{org}}$ was lowest at the beginning of the record, averaging -16.2 ‰, gradually increasing by 2.4 ‰ by 5 ka when $\delta^{13}\text{C}_{\text{org}}$ plateaued (Fig. 3.6C). $\delta^{13}\text{C}_{\text{org}}$ varied significantly over the last 3 ka, with an increase of 6.1 ‰ over the early Holocene from 0.9 to 0.5 ka. The trend for $\delta^{15}\text{N}$ follows a similar pattern as $\delta^{13}\text{C}_{\text{org}}$, with lower $\delta^{15}\text{N}$ in the earliest part of the record, averaging 2.4 ‰ around 8.3 ka, gradually increasing by 0.6 ‰ until 5 ka (Fig. 3.6D). $\delta^{15}\text{N}$ values at Cuobu peak at 4.5 ‰ in the last 1 ka and remain elevated.

3.4.4 Lipid Biomarkers

Sedimentary *n*-alkanes are valuable biomarkers, providing a record of past vegetation and the isotopic composition of regional precipitation and lake water. Short-chain C23 *n*-alkanes are derived from aquatic vegetation (Ficken et al., 2000; Seki et al., 2009) and were the most abundant throughout the record, with concentrations ranging from 510 to 98,208 ng/g (mean: 26,691 ng/g), but decreased sharply after 2 ka (Fig. 3.7A). C25 and C27 *n*-alkanes are a mixture of aquatic and terrestrial vegetation and averaged 19,395 ng/g and 18,036 ng/g respectively (Fig. 3.7B and 3.7C). Long-chain C29 and C31 *n*-alkanes are synthesized by terrestrial vegetation (Mügler et al., 2008; Seki et

al., 2009). Both C29 (range: 749-28920 ng/g) and C31 (range: 1051-32,072 ng/g) were less abundant than short-chain *n*-alkanes in the record, with averages of 14,717 and 12,672 ng/g respectively (Fig. 3.7D and 3.7E), with C31 increasing over the past 2 ka.

ACL values ranged from 27.2 – 28.6 throughout the early and middle Holocene (8.3 to 2 ka, mean: 27.6), increasing sharply after 2 ka, with a range of 28.8 – 29.6 (mean: 29.1; Fig. 3.7F). The ACL suggests that aquatic vegetation remained high until 2 ka, when the plant community shifted to a terrestrial dominated vegetation community. CPI showed a similar pattern, with low values, ranging from 3.7 – 6.9, from 8.3 – 2 ka (mean: 4.4; Fig. 3.7G). After 2 ka, CPI increased, ranging from 6.1 – 8.3 (mean: 6.5), suggesting a shift from aquatic to terrestrial vegetation dominated contributions to the lake.

At Cuobu, P_{aq} was highest from 8.3 to 2 ka, averaging 0.68 (range: 0.57 – 0.76), and decreased by 0.32 over the last 2 ka (Fig. 3.8H). P_{aq} concurs with the ACL and CPI indices that aquatic vegetation remained high until 2 ka when terrestrial vegetation inputs increased.

3.4.5 Hydrogen Isotopes

Leaf wax *n*-alkane hydrogen (δ^2H) isotopes provide information about precipitation and lake water isotope signatures. Short-chain *n*-alkanes δ^2H (*i.e.*, C23) are produced by aquatic vegetation that incorporate hydrogen directly from lake water, which integrates variations in the isotopic composition of lake water (in part due to evaporation and lake volume changes) as well as variations in precipitation (Liu and Liu, 2016; Mügler et al., 2008; Seki et al., 2009). Short-chain C23 *n*-alkane δ^2H (δ^2H_{C23}) averaged -248.2 ‰ and ranged between -263.0 to -235.2 ‰ over the record (Fig. 3.8A). δ^2H_{C23} was low from 8.3 to 5 ka, averaging -253.1 ‰, before increasing by ~15 ‰ to -268 ‰ from 5 to 2.5 ka. From 2.5 ka to present, δ^2H_{C23} showed high isotopic variability, with a shift towards wetter conditions around 2 ka, with the largest decrease around 1 ka to an average of -260.2 ‰.

Terrestrial vegetation utilizes soil water during its photosynthetic processes, which is isotopically similar to precipitation and is incorporated in long-chain *n*-alkane δ^2H (Xia et al., 2008). With more than 90% of precipitation at Cuobu derived from the ISM, variations in long-chain *n*-alkane δ^2H (*i.e.*, C29, C31) are inferred to reflect changes

in the monsoon (*e.g.*, Bird et al., 2014). Long-chain *n*-alkanes $\delta^2\text{H}_{\text{C}29}$ and $\delta^2\text{H}_{\text{C}31}$ exhibited similar trends as the short-chain *n*-alkanes (Fig. 3.8D-E). $\delta^2\text{H}_{\text{C}29}$ was lower from 8.3 to 6 ka, averaging -253.1‰, before gradually increasing to a mean of -245.3 ‰ at 2.5 ka. After 2.5 ka, $\delta^2\text{H}_{\text{C}29}$ decreased, remaining low until 1 ka (-258.6 ‰), after which $\delta^2\text{H}_{\text{C}29}$ subsequently increased and remained high until the present (mean: -244.9 ‰). $\delta^2\text{H}_{\text{C}31}$ was low from 8.3 to 5 ka (mean: -261.1 ‰), but subsequently increased after 2 ka, with an isotopic range between -267.5 to -237.0 ‰.

Mid-chain length $\delta^2\text{H}_{\text{C}25}$ and $\delta^2\text{H}_{\text{C}27}$, showed similar patterns to short-chain *n*-alkanes on millennial and centennial time scales, with lower values during the early Holocene (8.3 – 6 ka), with an isotopic range between -246.1 to -251.9 ‰ for $\delta^2\text{H}_{\text{C}25}$ and -247.2 to -250.7 ‰ for $\delta^2\text{H}_{\text{C}27}$ (mean: -250.0 ‰, mean $\delta^2\text{H}_{\text{C}27}$: -249.1 ‰; Fig. 3.8B). $\delta^2\text{H}_{\text{C}25}$ increased by 9.9 ‰ between 6 to 2.5 ka (mean: -239.6 ‰); while $\delta^2\text{H}_{\text{C}27}$ increased by 9.6 ‰ (mean: -239.5 ‰).

3.4.6 Effective Moisture

The delta-delta index ($\delta^2\text{H}_{\text{C}23-\text{C}31}$) estimates the ratio of precipitation:evaporation (P:E) $\Delta\delta^2\text{H}_{\text{C}23-\text{C}31}$ in Cuobu was variable, but generally low during the early Holocene from 8.3 to 5 ka, averaging -6.7, suggesting precipitation exceeded evaporation (high P:E; Fig. 3.8F). Higher frequency variability indicates that superimposed on this trend of a wetter (high P:E) early Holocene, there were two periods of higher P:E interspersed with lower P:E conditions. At 5 ka, $\Delta\delta^2\text{H}_{\text{C}23-\text{C}31}$ increased and remained elevated until 1 ka, averaging -1.6. From 1 to 0.5 ka, $\Delta\delta^2\text{H}_{\text{C}23-\text{C}31}$ decreased again, averaging -6.1, and then increased from 0.5 ka to modern, averaging -12.4.

3.4.7 Sedimentology

Several sedimentological proxies are used to assess changes in the input of clastic materials eroded from the watershed into the lake. Bulk density is a measurement of the mass of sediment per a given volume and has an inverse relationship with organic matter and water content (Brady, 1984). In the Cuobu core, bulk density was highly variable, ranging 0.01 – 3.5 g x cm⁻³ throughout the record (mean: 0.14 g x cm⁻³; Fig. 3.9A). Bulk

density was highest during the early Holocene from 8.3 to 6.5 ka, averaging 0.12 g x cm^{-3} and sharply declines around 6 ka and again from 4.5 to 3 ka.

Magnetic susceptibility (MS) ranged from -1.5 to $0 \text{ SI x } 10^{-5}$ and averaged $-0.78 \text{ SI x } 10^{-5}$ for the record (Fig. 3.9B). MS was higher from 8.3 to 5 ka (mean: $-0.62 \text{ SI x } 10^{-5}$) before decreasing from 5 ka to present (mean: $-0.9 \text{ SI x } 10^{-5}$), with a sharp increase around 1 ka. High frequency variability of MS follows bulk density, indicating a stronger relationship between these proxies.

Both %clay and %silt was lower from 8.3 to 5 ka, with %clay ranging from 0.43 % to 20.8 % and %silt ranging from 5.7 % to 82.1% (mean: clay: 6.7 %; silt: 45.7 %; Fig. 3.9C and 3.9D). From 5 ka to present, %clay and %silt increased by 3.7 % and 12.6 % respectively (5 ka – present; mean %clay: 10.4 %; %silt: 59.8 %). Percent sand, showed the opposite trend of %clay and %silt, ranging 1.4 % to 93.6 % from 8.3 to 5 ka (mean: 47.6 %) and decreased from 5 ka to present by 17.5 % (mean: 29.7 %; Fig. 3.9E). A histogram of the grain size diameters shows that the Cuobu record had higher abundances of coarse sediments from 8.3 to 4.5 ka when the distribution abruptly shifts to favor finer sediments (Fig. 3.9F). Finer sediments were more abundant until 1 ka with short periods of coarser sediment influxes.

3.4.8 X-ray Fluorescence (XRF) Geochemistry

Of the forty-nine elements measured using XRF, I focus here on titanium (Ti), and zirconium (Zr). Ti and Zr are both conservative elements that are associated with lithic materials, with increased concentration of any of these elements being associated with greater terrestrial sediment inputs into the lake environment (Chassiot et al., 2018; Croudace et al., 2006; Cuven et al., 2010; Löwemark et al., 2011; Nesbitt and Markovics, 1997; Roberts et al., 2019). In the Cuobu record, Ti shows a pattern of higher concentrations during the early Holocene, ranging from 9348 – 18,577 cps (mean: 14,436 cps), than gradually decreased from 6 to 2.5 ka by 6270 (mean: 8165 cps; Fig. 3.9G). Ti concentrations increased again by 1929 in the late Holocene around 2.5 ka and remained high until present (mean: 10,121 cps). Zr showed a similar pattern as Ti, with higher concentrations in the early Holocene (8.3 – 6 ka) ranging from 430 to 1573 cps (mean: 927 cps; Fig. 3.9H). Average Zr gradually decreased by 353 from 6 to 3 ka when average

Zr increased again by 88.3 from 3 ka to present (mean: 661 cps). The full XRF dataset are in Appendix 2 Tables A 2.1 – 2.6.

3.4.9 Statistical Analysis

A Principal Components Analysis (PCA) was performed on select data from Cuobu including lithics, TOM and TC, *n*-alkane concentrations and their metrics (ACL, CPI, P_{aq}), $\Delta\delta^2H_{C23-C31}$, C:N ratios, and $\delta^{13}C$ and $\delta^{15}N$ isotopes. All data were normalized using a z-score with the mean subtracted from each value and divided by the standard deviation. The distribution of proxies as evidenced in a biplot of the PCA, shows the grouping of proxies and their relation to each other as they are correlated with the two principal components (Fig. 3.10). Principal Component 1 (PC1) accounts for 40.6% of the variability in the dataset, while Principal Component 2 (PC2) accounts for an additional 16.1% of the dataset variability. The PCA biplot shows that fine sediments (%clay and %silt), *n*-alkane concentrations ($nC_{23} - nC_{29}$) and TC are all positively correlated with PC1 and PC2 (top right quadrant). P_{aq} , BD, and TOM are positively correlated with PC1 and negatively correlated with PC2 (bottom right quadrant). C:N, $\delta^{13}C$, $\delta^{15}N$, %lithics, ACL, CPI, δ^2H_{C23} , and Ti are all positively associated with PC1 and negatively associated with PC2 (top left quadrant). %sand, MS, Zr, mid-chain and long-chain *n*-alkane hydrogen isotopes ($\delta^2H_{C25} - \delta^2H_{C25}$) are all negatively associated with PC1 and PC2 (bottom left quadrant). A second PCA was conducted only on grain size proxies, %clay, %silt, and %sand, and the time series of PC1, which accounts for % of the dataset variability, closely follows the same trends as %sand.

3.5 Discussion

3.5.1 Inferred ISM Precipitation & Evaporation on the South-Central Tibetan Plateau

Leaf-wax *n*-alkane δ^2H show pronounced shifts in ISM strength and P:E balance at Cuobu during the last 8 ka. δ^2H isotopic composition is controlled by the amount of precipitation and the moisture source (Sachse, 2012), with lower δ^2H values inferred as greater precipitation. With terrestrial plants incorporating ISM precipitation during the growing season, I interpret δ^2H_{C31} as a signal of monsoon intensity over the region. At

Cuobu, low $\delta^2\text{H}_{\text{C}31}$ values suggest a strengthened ISM from 8.3 to ~5 ka, after which high $\delta^2\text{H}_{\text{C}31}$ indicates a weakened ISM from 5 to 1 ka. From 1 ka to the present, lower $\delta^2\text{H}_{\text{C}31}$ suggests a slight strengthening of the ISM. The interpretation of short-chain *n*-alkanes $\delta^2\text{H}_{\text{C}23}$ is more complex, with lake water incorporating the isotopic signals of evaporation and the ISM. Lake water isotopes ($\delta^2\text{H}_{\text{C}23}$) at Cuobu showed similar long-term trends as $\delta^2\text{H}_{\text{C}31}$, indicating that the isotopic composition of lake water largely tracked that of precipitation during the Holocene. Supporting wet local conditions between 8 and 5 ka, the $\text{D}\delta^2\text{H}_{\text{C}23-\text{C}31}$ record shows low values, indicating a positive P:E balance at Cuobu at the same time that the ISM was strengthened (low $\delta^2\text{H}_{\text{C}31}$). While most of this period had higher effective moisture, there was a noted increase in the P:E balance between 6.2 to 6 ka, which corresponds to a drop in the C:N ratio, that indicates drought conditions locally. Following early Holocene pluvial conditions, $\text{D}\delta^2\text{H}_{\text{C}23-\text{C}31}$ shows a sharp increase between 5.5 and 4.5 ka, indicating a decrease in the local P:E balance that occurred when ISM intensity was also diminished (high $\delta^2\text{H}_{\text{C}31}$). A decrease in the $\Delta\delta^2\text{H}_{\text{C}23-\text{C}31}$ record after 1 ka additionally supports wetter conditions locally from ~1 ka to the present that coincides with a suggested strengthening of the ISM during this time in the $\delta^2\text{H}_{\text{C}31}$ timeseries.

The interpretation of local hydroclimate is supported by the aquatic and terrestrial vegetation proxies. The $\delta^{13}\text{C}_{\text{org}}$ record suggests a high contribution of aquatic and/or C_3 land plants from 8.3 to 5 ka, after 5 ka there was a higher influx of C_4 plant terrestrial vegetation productivity inputs to the lake, with terrestrial vegetation dominating over the last 1 ka. This corresponds to a shift from higher C:N ratio from 8.3 to 2 ka to lower C:N 2 ka to present, suggesting a shift from larger aquatic plants to planktonic aquatic productivity. The $\delta^{15}\text{N}$ record productivity interpretation, like the $\delta^{13}\text{C}_{\text{org}}$ record, indicates high aquatic productivity between 8.3 and 5 ka, with terrestrial vegetation inputs increasing throughout the middle and late Holocene with highest terrestrial productivity over the last 1 ka.

Wet conditions at Cuobu in the early Holocene correspond to high aquatic productivity from 8.3 to 5 ka indicated by high concentrations of short-chain *n*-alkanes (C_{23}) and lower $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$. Productivity shifted to terrestrial dominated vegetation inputs in Cuobu during the middle and late Holocene, with a mixed aquatic and terrestrial

vegetation signal indicated by $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ from 5 to 1 ka, while the *n*-alkanes concentrations shifted abruptly to higher long-chain concentrations between 2.5 and 2 ka. The decline in *n*-alkane derived aquatic productivity around 2.5 ka occurred much later than the shift to drier conditions indicated by $\delta^2\text{H}_{\text{C}_{31}}$ and $\Delta\delta^2\text{H}_{\text{C}_{23}-\text{C}_{31}}$ or the mixed-vegetation signal suggested by the $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ isotope data. The difference in the timing between these vegetation proxies suggest that after ISM precipitation and effective moisture declined around 5 ka lake levels began to decline, but remained high enough to support a shift in vegetation communities from more aquatic planktonic species to a mixture of emergent and submerged macrophytes with terrestrial vegetation.

3.5.2 Monsoon-induced Cuobu River Overflow

Grain size variations are typically interpreted as reflecting either lake level change (Bird et al., 2017; Bird et al., 2014; Dearing, 1997; Digerfeldt, 1986; Shuman et al., 2001; Shuman et al., 2009) or the energy and amount of runoff entering a lake (Conroy et al., 2008). While, other lake-based paleoclimate studies from the Tibetan Plateau (TP) have interpreted grain size proxies, %sand in particular, as lake level indicators (Bird et al., 2017; Bird et al., 2014), this does not appear to be the case at Cuobu. If interpreted in terms of lake level, the Cuobu sand record would suggest low lake levels between 8.3 and 4.5 ka and after 1 ka and high lake levels from 4.5 to ~1 ka. This pattern of Holocene hydroclimate variability stands in stark contrast to the multitude of other ISM reconstructions from the TP that indicate a strengthened monsoon, in agreement with the $\delta^2\text{H}_{\text{C}_{31}}$ record at Cuobu, and high lake levels during this time (Bird et al., 2017; Bird et al., 2014; Herzschuh et al., 2009; Zhu et al., 2008). Instead, I contend that the Cuobu sand records reflect changes in monsoon-derived runoff entering the lake whereby increased monsoonal runoff delivered greater quantities of sand and vice versa. This interpretation is consistent with lower $\delta^2\text{H}_{\text{C}_{31}}$ and $\Delta\delta^2\text{H}_{\text{C}_{23}-\text{C}_{31}}$ between 8.3 and 4.5 ka, which respectively indicate intensified monsoonal precipitation and greater effective moisture at Cuobu when sand abundances were high. High frequency variability in %sand between 8.3 and 4.5 would indicate that runoff was highly variable during the early Holocene through the early half of the middle Holocene, with high runoff from 8.3 to 6.2 ka and 6 ka to 4.5 ka while runoff declined from 6.2 to 6 ka. Conversely, decreased sand

abundances between 4.5 and 1 ka occurred when $\delta^2\text{H}_{\text{C31}}$ and $\Delta\delta^2\text{H}_{\text{C23-C31}}$ increased, indicating a reduction in sand when monsoonal intensity weakened and effective moisture decreased. The Ti and Zr records further support interpreting sand abundances in terms of terrestrial eroded sediments and surface runoff to the lake. Higher titanium and zirconium concentrations from 8.3 to 5 ka corresponded with high %sand, with the influx of sand and terrestrial sediments co-occurring with wetter conditions at Cuobu as indicated by the $\Delta\delta^2\text{H}_{\text{C23-C31}}$ record.

Determining the mechanism responsible for Holocene sedimentology at Cuobu, with coarser sediments inferred as runoff, requires an understanding of the physical environment. The geomorphology of the site shows that Cuobu formed behind glacial moraines that both dammed the valley and separated the lake from the Cuobu River. One of the ephemeral tributaries to the lake is a dry stream channel that cuts across the moraine and forms a delta into the lake; connecting Cuobu with the Cuobu River. I suggest that the geomorphological setting of Cuobu is the primary driver of the grain size signal. Increased sand at Cuobu during a period of stronger monsoon intensity can be attributed to an influx of sediment from the Cuobu River. During the early Holocene ISM maximum, this stream could have been an important source of sediments to the lake and is closer to the core sites than the other tributaries, which supports coarser sediments influxes coming from this stream channel. Cuobu River is situated at a higher elevation than the lake, but at a lower base elevation than the moraine crest, requiring high river discharge to breach the moraine, contributing a flow of water and coarser sediments directly into the lake through the ephemeral stream channel. Modern observations of the site show that the overflow channel could have accommodated large water volumes and is perfectly situated at the lowest point of the moraine at the junction between the moraine and the mountain spur where the braided channel formed. In the early Holocene, increased ISM precipitation may have increased fluvial discharges and contributed to overland flooding. River height would need to be 5 m higher than modern water levels for overbank flooding to breach the moraine and connect the overflow tributary to the lake. When monsoon intensity declined during the middle Holocene, water levels fell at both Cuobu and Cuobu River disconnecting the flow of water and coarse sediments from river to the lake.

3.5.3 Synoptic vs. Local Hydroclimate at Cuobu

Cuobu shows a strong agreement between synoptic and local hydroclimate proxies, with millennial scale trends in ISM variability indicating pluvial (wet) conditions from 8.3 to 5 ka and 1 ka to present and drought conditions from 5 to 1 ka. Higher frequency variability during the early Holocene shows pluvials from 8.3 to 6.2 ka and again from 6 to 5 ka with drought conditions from 6.2 to 6 ka. Pluvials at Cuobu are indicated by high %sand, low $\Delta\delta^2\text{H}_{\text{C31}}$, high P:E balance (low $\Delta\delta^2\text{H}_{\text{C23-C31}}$), and increased aquatic productivity. Drought conditions are indicated by low %sand, high $\Delta\delta^2\text{H}_{\text{C31}}$, low P:E balance, and higher terrestrial vegetation inputs. PCA of the Cuobu synoptic and local hydroclimate proxies supports the association of fine sediments with TOM and *n*-alkane concentrations (C23 – C29) and coarse sediments are associated with mid-chain and long-chain *n*-alkane hydrogen isotopes ($\delta^2\text{H}_{\text{C25}} - \delta^2\text{H}_{\text{C31}}$). P:E balance ($\Delta\delta^2\text{H}_{\text{C23-C31}}$) is associated with short-chain *n*-alkane $\Delta\delta^2\text{H}_{\text{C23}}$, long-chain *n*-alkane concentrations (C31), $\delta^{13}\text{C}$, $\delta^{15}\text{N}$, ACL and CPI. A PCA of the grain size measurements was used to assess the time series of the sedimentology at Cuobu, with the PC1 time series strongly reflecting the %sand record (Fig. 3.11B). The strong relationship between synoptic and local hydroclimate proxies, with changes in large-scale monsoon drivers having an immediate impact on local monsoon expression, has also been observed in other hydroclimate records from the Tibetan Plateau (Bird et al., 2014).

To better understand spatiotemporal ISM variability on the Tibetan Plateau, I compare the Cuobu record with high-resolution paleoclimate records from Paru Co (Bird et al., 2014). A high elevation lake from the southeastern plateau, Paru Co (29.796°N, 92.352°E, elevation 4845 m a.s.l.; 520 km east of Cuobu) is a precipitation and lake level record for the last 11 ka in southeastern Tibet (Bird et al., 2014). Similar to Cuobu, long-chain *n*-alkane $\delta^2\text{H}_{\text{C27}}$ and $\delta^2\text{H}_{\text{C29}}$ indicate strengthened ISM precipitation at Paru Co until 5 ka when ISM intensity declined. Lake levels at Paru Co, as interpreted from %sand, and runoff intensity, interpreted from %lithics, also show similar trends with the Cuobu record. Specifically, runoff was high during the early and the late Holocene at Paru Co (8.3 – 7 and 1.5 – 0.5 ka), while lake levels remained high throughout the early and middle Holocene (8.3 – 5 ka). The centennial scale variability at Paru Co also shows agreement with Cuobu, with deeper lake levels and increased runoff at Paru Co

coinciding with higher %sand and greater effective moisture (low P:E) from 8.3 to 6.2 ka, after which lake levels and runoff at Paru Co decreased in conjunction with lower runoff and effective moisture at Cuobu. Runoff at Paru Co increased from 1.5 and 0.5 ka indicating an increase in monsoon intensity, which corresponds with higher effective moisture and increased %sand at Cuobu. A late Holocene increase in ISM intensity was also observed at another eastern TP lake, Nir'Pa Co, with increased %lithics and %sand over the last 1 ka indicating a stronger monsoon (Bird et al., 2017). These trends in local hydroclimate were driven, not only by synoptic ISM dynamics, but also local climate conditions including temperature.

3.5.4 Millennial & Orbital Scale Drivers of ISM Variability

Holocene ISM variability has been attributed to multiple drivers, including solar insolation, the migration of the ITCZ, and the ocean-atmosphere system. Northern Hemisphere (NH) solar insolation was highest during the early Holocene and began to decline around 8 ka (Berger and Loutre, 1991), which drove the southward migration of the ITCZ (Fleitmann et al., 2003; Haug et al., 2001) and cooler temperatures on the plateau (Herzschuh et al., 2009; Herzschuh et al., 2006). ITCZ record at Qunf Cave in Oman (17°10'N 54°18'N), shows that the ITCZ slowly migrated south from 8.3 ka until 5 ka (Fleitmann et al., 2003). The southward latitudinal displacement of the ITCZ stabilized from 5 to 3 ka, coinciding with the decline in effective moisture at Cuobu.

In addition to isolation-forced ITCZ variability, changes in the ocean-atmosphere system play a leading role in millennial and higher-frequency ISM variability. A strong sea surface temperature (SST) gradient in the equatorial Pacific (La Niña-like state: cool eastern and warm western equatorial Pacific) during the Holocene between 11 and 4 ka, for example, corresponded with enhanced ISM intensity, greater effective moisture, and high lake levels across much of the Tibetan Plateau (Conroy et al., 2008; Koutavas and Sachs, 2008; Marchitto et al., 2010; Moy et al., 2002). After 4 ka, the SST gradient reversed (El Niño-like state: warm eastern and cool western equatorial Pacific), which corresponded to reduced ISM intensity, lower effective moisture and lake levels across the Tibetan Plateau, and weaker ISM winds that reduced upwelling in the Arabian Sea (Gupta et al., 2003). The co-occurrence of pluvial conditions on the TP during La Niña-

like conditions is consistent with modern climatic relationships between the Tropical Pacific and ISM with weak annual monsoons linked to El Niño events and strong annual monsoons corresponding with La Niña events (Chowdary et al., 2016; Samanta et al., 2020; Surendran et al., 2015).

These orbital drivers of ISM variability are reflected in the millennial scale trends of synoptic and local hydroclimate at Cuobu. Wet conditions at Cuobu during the early Holocene ISM maximum were driven by high insolation and the northerly ITCZ, while the middle Holocene transition to dry conditions around 5 ka corresponds with drier conditions at other sites on the Tibetan Plateau and evidence of weakening ISM precipitation and winds throughout the region (Bird et al., 2014; Cai et al., 2012; Fleitmann et al., 2003; Fleitmann et al., 2007; Herzschuh et al., 2009). The timing of the middle Holocene transition at Cuobu shows that runoff (%sand) and P:E balance abruptly shifted in response to reduced solar insolation, the southward migration of the ITCZ, and the shift to El Niño-like conditions in the Pacific. Lake levels at Paru Co also decreased at this time, indicating that local hydroclimate on the southeastern TP was consistent at these sites that are over 500 km apart. While there is strong agreement with these orbital drivers on ISM expression at Cuobu on longer time scales, these drivers do not account for the higher-frequency variability seen in the Cuobu record, particularly during the early and late Holocene.

3.5.5 Drivers of Decadal & Centennial ISM Variability

Higher frequency variability at Cuobu is superimposed on the millennial trends of a wet early and late Holocene and a dry middle Holocene, which is driven by centennial and decadal scale variability in local climate and SSTs. Local hydroclimate is reflective of local and regional precipitation, temperature, and evaporation patterns. Temperature and effective moisture records from the Tibetan Plateau help explain how local climate can drive regional monsoon expression. One temperature record from the Tibetan Plateau at Lake Zigetang (90.9°E 32.0°N, 463 km northeast of Cuobu), shows that the early Holocene was a warm, humid environment as inferred by dominant temperate steppe vegetation (Herzschuh et al., 2006). After 5 ka, the eastern Tibetan Plateau transitioned to a drier, cooler environment; while there was a modest warming over the last 1 ka. This

warming over the last 1 ka corresponds to the decline in effective moisture seen at Cuobu, suggesting that higher evaporation reduced effective moisture even as monsoon intensity increased.

The Koucha Lake temperature and effective moisture pollen record (97.2 °E 34.0°N, 1,090 km northeast of Cuobu) also showed warmer, wetter conditions in the early Holocene until 7 ka, when effective moisture began to gradually decline (Herzschuh et al., 2009). Koucha Lake also supports a drier, arid hydroclimate in the eastern Tibetan Plateau during the middle and late Holocene (5 ka to modern), as evident in the Cuobu $\Delta\delta^2\text{H}_{\text{C23-C31}}$ record from 5 to 1 ka. A persistently drier, more evaporative middle and late Holocene is also evident in the ISM record at Tianmen Cave (90°4'E, 30°55'N; Fig. 3.12C) at the easternmost edge of the Tibetan Plateau (Cai et al., 2012). ISM intensity at Tianmen Cave gradually declined after ~ 7 ka with a hiatus in the record between 3.5 and 1 ka; indicating a drier climate in eastern Tibet from 7 to 1 ka. Calcite precipitation restarted temporarily around 1 ka, simultaneous with the higher effective moisture at Cuobu, increased runoff at Cuobu and Paru Co, and deeper lake levels exhibited at Nir'Pa Co (Bird et al., 2017).

Centennial monsoon variability at Cuobu during the early and late Holocene can be attributed to both local temperature records as well as SSTs. Early Holocene pluvials from 8.3 to 6.2 ka and 6 to 5 ka coincide with warmer temperatures and La Niña-state in the equatorial Pacific, while drought conditions from 6.2 to 6 ka correspond with colder temperatures on the TP and an El Niño-like state. Late Holocene increases in effective moisture and runoff at Cuobu from 1 ka to present are reflective of relatively warmer temperatures on the plateau with highly variable shifts between La Niña and El Niño-like states. Coherent patterns in centennial scale local hydroclimate between Tibetan Plateau records at Cuobu and Paru Co indicate that monsoon expression in the southeastern-southcentral Tibetan Plateau is strongly impacted by the land-sea thermal gradient. Warmer temperatures on the Tibetan Plateau and the Pacific Ocean are projected to continue and increase with climate change, threatening to suppress the land-sea thermal gradient that is a mechanical driver of the ISM (Kumar et al., 2006; Li et al., 2017; Sharmila et al., 2015). The Cuobu record shows that the land-sea gradient is an important driver of short-term scale variability in the ISM, with the suppression of this gradient

potentially driving a weaker monsoon expression and drier local hydroclimate conditions on the Tibetan Plateau in the future.

3.6 Conclusions

The multi-proxy Cuobu paleoclimate record indicates that the lake has experienced significant hydroclimate variations over the last 8.3 ka. Sedimentological indicators show that Cuobu had increased runoff in the early Holocene that abruptly decreased around 4.5 ka as indicated by a shift from coarser to finer dominated sediments. This runoff is attributed to increased discharge in the Cuobu River, which runs parallel to the lake, under a stronger ISM that breached the moraine that separates the river from the lake. The river contributed coarse sediments to the lake until monsoon intensity and water levels dropped around 4.5 ka, isolating the river from the lake and decreasing the discharge of coarse sediments and stream flow into the lake. Leaf-wax *n*-alkane isotopes support the interpretation of strong monsoon intensity in the early and late Holocene and weak monsoon intensity in the middle Holocene. $\Delta\delta^2\text{H}_{\text{C23-C31}}$, a proxy for effective moisture and the ratio of precipitation to evaporation, shows more effective moisture between 8.3 and 4.5 ka and 1 ka to present. Effective moisture was lower from 4.5 to 1 ka corresponding to a decline in ISM intensity observed in records across the Tibetan Plateau. The timing of the synoptic and local hydroclimate response to changes in the monsoon intensity are in-sync, suggesting a simultaneous response to large-scale orbital changes in the ISM. Both monsoon intensity and effective moisture increased after 1 ka, however, this increase was insufficient to reconnect the two water bodies. The timing of this decline in monsoon intensity corresponds to records across the Tibetan Plateau that show a decline in effective moisture around 5 ka and a shift to a cooler, drier hydroclimate that persisted until the monsoon intensity increased around 1 ka. The synchronous decline in ISM intensity around 5 ka in the southern central and eastern Tibetan Plateau occurs at the same time as the migration of the ITCZ in response to the reduction of solar insolation and warming conditions in the Pacific similar to an El Niño-like state.

4. MULTI-PROXY EVIDENCE FOR AN EARLY HOLOCENE LOW LAKE STAND DURING A STRONG MONSOON: INVESTIGATING THE ELEVATION DEPENDENT EXPRESSION OF THE INDIAN SUMMER MONSOON ON THE TIBETAN PLATEAU

4.1 Introduction

Understanding hydroclimate variability in the Third Pole Environment, which encompasses the Tibetan Plateau and the surrounding region (Qui, 2008), is important for establishing how climate change impacts water availability for over a third of the world's population. The Indian Summer Monsoon (ISM) is the primary source of precipitation in the Third Pole region, with as much as 90% of annual precipitation falling during the boreal warm season between May and September (Tian et al., 2007). There is considerable evidence from paleoclimate archives that ISM intensity has varied throughout the Holocene and that there have been abrupt changes in its mean state from pluvials (wet phases) to droughts and vice versa. After an early Holocene maximum in precipitation from 11.7 to 7, ISM precipitation declined between 7 and 5 ka, with isotopic proxies indicating a gradual decline while sediment proxies indicating a more abrupt transition (Berkelhammer et al., 2012; Bird et al., 2017; Bird et al., 2014; Fleitmann et al., 2003; Fleitmann et al., 2007; Herzschuh et al., 2006). The middle Holocene transition to a weakened monsoon between 7 to 5 ka has been attributed to reduced solar insolation (Fleitmann et al., 2003) that resulted in a southward migration of the ITCZ (Haug et al., 2001) and increased El Niño-like conditions in the Pacific (Chen et al., 2016; Conroy et al., 2008; Emile-Geay and Tingley, 2016; Emile-Geay et al., 2016; Moy et al., 2002).

While many records agree that the ISM weakened during the middle Holocene (7 – 5 ka), questions remain about the elevation-dependent expression of this decline in monsoon intensity (Bird et al., 2014; Herzschuh et al., 2006). This is in part because there are few decadal-resolved records of ISM dynamics (Berkelhammer et al., 2012; Cai et al., 2012; Zhu et al., 2008) and even fewer decadal-resolved records found directly on the Tibetan Plateau, with most of these records in high-elevation regions (Bird et al., 2017; Bird et al., 2014). High-resolution records allow for the investigation of hydroclimate processes that occur on shorter time scales and capture variability missed by records

resolved on centennial and millennial time scales. Monsoon precipitation has also been shown to vary between synoptic and local hydroclimate proxies, with evidence to suggest that isotopic records (synoptic) show earlier decline than local, sedimentological proxies (Berkelhammer et al., 2012; Bird et al., 2017; Bird et al., 2014; Fleitmann et al., 2003; Herzschuh et al., 2009; Herzschuh et al., 2006), with evidence that the monsoon contracted during the middle Holocene transition with reduced precipitation and upwelling evident in the Arabian Sea and Arabian Peninsula (Fleitmann et al., 2003; Gupta et al., 2003). It is difficult to determine how this is reflected on the Tibetan Plateau since records are frequently from central and eastern Tibet, with limited records further east towards the Hengduan Mountains, a highly populated area of the Plateau. Low-resolution pollen and tree-ring records from the Hengduan Mountains are from high-elevation sites (Fan et al., 2008; Fan et al., 2009), and therefore may not necessarily reflect hydroclimate variability affecting lower elevation intermontane areas where populations are centered. Limited understanding of Holocene monsoon expression in these low-elevation, highly populated areas of the Tibetan Plateau reduces the accuracy of future monsoon rainfall projections under climate change.

Here I present a high-resolution, low elevation (2810 a.s.l.) sediment record from Galang Co (Fig. 4.1), an inter-montane valley lake in the Hengduan Mountains. The Galang Co record spans the last 12.3 ka and was developed to understand the expression of the ISM along elevational gradients across the eastern Tibetan Plateau. Local hydroclimate conditions throughout the Holocene was reconstructed using sedimentology, organic matter, X-ray fluorescence (XRF) geochemistry, and long- and short-chain leaf-wax *n*-alkane hydrogen isotopes. This record addresses: 1) hydroclimate variability at an under-represented area of the southeastern Tibetan Plateau, 2) how the expression of ISM precipitation differs between low and high elevation sites and across the eastern Tibetan Plateau, and 3) how the timing of the transition to a weak monsoon differs between synoptic and local ISM hydroclimate proxies.

4.2 Study Area: Galang Co

Galang Co is a small (0.1 km²), low elevation lake (2810 a.s.l.) within the Hengduan Mountains of the southeastern Tibetan Plateau (Fig 4.2A, 29.90817° N,

95.60391° E). The lake is situated near the bottom of a deep valley at the confluence of the Parlung Zangpo and Quzong Zangpo rivers and surrounded by steep mountain terrain with nearby peaks rising to over 5900 m a.s.l. The lake's small watershed (4.2 km²) consists of steep mountain slopes (4150-3750 m a.s.l.) to the northwest with a smaller hill (2900 a.s.l.) to the south of the watershed. Geomorphological observations of the lake's watershed made in the field and from satellite images show scarp features on the mountain along the north side of the lake and the heterogeneous mixture of rocks within the hill formation on the south edge of the lake that are suggestive of an ancient landslide. There are no geomorphic features that would suggest any additional landslides and there are no landforms indicating glaciation in the watershed (Fig. 4.2B). Historical markers observed in the area suggest that the watershed was the home of the Galang or Tubo Dynasty which existed from around 700 CE to the early 20th century. Today, a small village (est. population = 100) exists along the outlet of the lake, utilizing the Galang Co watershed for grazing and small-scale agriculture.

Field observations during coring indicate that Galang Co's bathymetry consists of a broad wetland and littoral zone that sharply transitions to a deep central basin with a maximum depth of 18 m. The inlet on the southwest corner of the lake is modified with an 8-foot stone structure, extending a few feet above the water level, powering prayer wheels at a stupa on the southwest edge of the lake. There is no impoundment present behind the structure, indicating that it does not impact lake levels. The littoral zone of the lake is densely vegetated with aquatic macrophytes, while the vegetation immediately surrounding the lake is comprised of thick groundcover vegetation, including ferns and mosses. The watershed of the lake transitions from wetland to a mixed deciduous-coniferous forest, which covers the rest of the watershed, including the surrounding slopes. This is consistent with the broader vegetation pattern of the region with montane-needle and broadleaf forests in the southeastern plateau below 3000 m elevation (Herzschuh et al., 2006). The northern shore of the lake transitions into a shallow wetland where water collects from the steep mountainside.

Modern regional climate data is derived from the Qamdo station (3307 m a.s.l.; 31.15° N, 97.167° E), which is ~220 km from Galang Co. Regional precipitation totals 367 mm and tracks the seasonal ISM cycle, with 89% of rainfall occurring between May

and September (330 mm; average summer temperature = 15.4°C; Fig. 4.3). Winters (December-February) are characterized by low precipitation (2.1 mm) and cold temperatures (-0.7 – 1.8°C), with winter ice cover on the lake from at least December through February.

4.3 Methods

4.3.1 Sample Collection

Sediment cores, water samples, surface sediments, and vegetation were collected at Galang Co in June 2015. The surface water chemistry of the lake was close to neutral (pH = 7.82) while conductivity and turbidity were low. Dissolved oxygen was 6.1 mg/L and the temperature was 17°C. Three surface sediment cores that captured the sediment-water interface were retrieved using a piston surface corer (Fig. 4.2). A 114 cm surface core, E-15, was acquired at a water depth of 17.3 m, while two shorter surface cores, A-15 (102 cm) and B-15 (115 cm), were collected at water depths of 17.5 m. The top 27 cm of E-15 were extruded at 1 cm intervals in the field while A-15 and B-15 were secured with Xorbitol[®] gel for transport and split at the Paleoclimatology and Sedimentology Laboratory at Indiana University-Purdue University Indianapolis (IUPUI). A longer sediment core, D-15, was retrieved from 17.7 meter water depth using a modified Livingstone piston corer (composite core length = 294 cm) (Livingstone, 1955; Wright, 1967). D-15 consisted of four-1 m drives that were overlapped by 30 cm in order to ensure complete sediment recovery. A replicate Livingstone core C-15 (composite core length = 266 cm; water depth=17.5 m) was also retrieved with a 30 cm overlap. Composite cores were made using a combination of field depths, images, and magnetic susceptibility to identify and correlate lithological units between drives.

Water samples were collected for isotopic analysis, while water chemistry, including temperature, pH, alkalinity, and conductivity, was measured in-situ using a Hydrolab MS5. Modern sediments from the surface-water interface were collected from the deep and shallow basins using an Ekman grab sampler. Two soil samples were also collected from the surrounding watershed. Samples of aquatic and terrestrial vegetation communities within and surrounding the lake were additionally collected. All samples

were stored at 4°C before analysis at the Paleoclimatology and Sedimentology Laboratory at IUPUI.

4.3.2 Geochronology

Sediments were dated using a combination of ^{210}Pb , ^{214}Pb , ^{137}Cs , and ^{14}C radiometric techniques. The ^{210}Pb , ^{214}Pb , and ^{137}Cs activities were measured by direct gamma counting on 13 samples from the upper 35 cm of the E-15 surface core at the University of Pittsburgh (Appleby and Oldfield, 1978). Radiocarbon (^{14}C) dates of charcoal samples from the D-15 core ($n = 9$) were determined using accelerator mass spectrometry (AMS) at the Keck AMS Facility, University of California Irvine. Charcoal samples were isolated by wet sieving at 63 μm before undergoing acid-base-acid (1 N HCl and 1 N NaOH) pretreatment based on UCI protocols (KCCAMS, 2011; Olsson, 1986). Radiocarbon dates were calibrated using the IntCAL 13 dataset (Reimer et al., 2013) and an age model was produced using the Bacon software program (Blaauw and Christen, 2011). All dates for the Galang Co E-17 and D-17 composite core are reported in calendar years before present (0 ka; 0 ka = 1950 CE).

4.3.3 Initial Core Description

All cores were split, imaged, and described before sub-sampling. High resolution images of the cores were made at IUPUI using a GeoTek Multi-Sensor Core Logger. Volumetric samples (1 cm^3) were collected from the work half of all cores at 1 cm intervals, weighed, and dried at 60 °C for 24 hours before being reweighed to determine dry bulk density (ρ_{dry} ; g/cm^3) and water content (%water). The sediment was then combusted at 550 °C for four hours, weighed, combusted again at 1000 °C for two hours, and weighed again in order to calculate total organic matter (%TOM) and total carbonate (%TC) from weight loss (Boyle, 2001; Heiri et al., 2001). The surface cores were then sliced into sections at a 1 cm resolution while Livingstone cores were sliced into 0.5 cm section for further analysis.

4.3.4 Grain Size

Approximately ~1 g of wet sediment was taken from cores E-15 and D-15 cores at 1 cm intervals, and from homogenized samples of the surface sediments and soil samples for grain size analysis. The samples were dried at 60 °C for 24 hours before weighing. Organic matter was removed by soaking the samples in 30 % hydrogen peroxide (H₂O₂) for 24 hours at room temperature before treating them with up to 5-20 ml aliquots of 30 % H₂O₂ at 70°C (Gray et al., 2010). Biogenic silica was then removed from the samples by soaking them in 20 mL of 1 N NaOH for six hours at 60 °C. The samples were subsequently centrifuged and rinsed with DI H₂O to remove any trace NaOH before freeze drying and reweighing to calculate lithics (%). Because carbonates were not present, the samples were not treated with HCl. Samples were lastly stored in 2.5% sodium metaphosphate and sonicated before grain size analysis, which was conducted using a Malvern Mastersizer 2000 at IUPUI. Grain size results were reported in a range of 49 particle diameter size bins between 0.2 and 2000 µm with an average of three replicates per sample.

4.3.5 XRF Geochemistry

Sedimentary geochemistry for elements ranging between aluminum (Al) to uranium (U) (atomic numbers 13 – 92) were measured using scanning x-ray fluorescence (XRF) at 0.5 cm resolution. XRF analysis was conducted at the Large Lakes Observatory, University of Minnesota Duluth using an ITRAX XRF Core Scanner (Croudace et al. 2006). Cores were scanned using a Cr source tube (30 kV; 55 mA) with a 15 second dwell time and a 10 mm measurement resolution. Raw data was processed using Qspec 8.6.0 software. All measurements are reported as counts per second (cps).

4.3.6 Carbon and Nitrogen Isotopes

Samples from the composite E-15 and D-15 core were collected at 2 cm intervals (n=148), dried, homogenized, and weighed into tin capsules (~4 mg) before C and N isotopic analysis at the Large Lakes Observatory, University of Minnesota Duluth. Measurements of total organic carbon (TOC), total nitrogen (TN), organic $\delta^{13}\text{C}$, and $\delta^{15}\text{N}$ were made using a Thermo Finnigan Delta Plus XP Isotope Ratio Mass Spectrometer

(IRMS) combined with a Costech 4010 elemental combustion system. Measurements are reported as per mil (‰) with $\delta^{13}\text{C}$ relative to the Vienna Pee Dee Belemnite (VPDB) and $\delta^{15}\text{N}$ relative to atmospheric nitrogen. A series of standards were used including acetanilide, caffeine, B-2153, B-2159, and USGS41 (National Institute of Standards and Technology) with coefficient of variation for C and N ranging between 0.5-1.1 %. Isotopic precision for standards was 0.03-0.26 ‰ for N measurements and 0.05-0.18 ‰ for C.

The carbon isotopic composition of organic matter ($\delta^{13}\text{C}_{\text{org}}$) is often used in conjunction with C:N to distinguish between C3 and C4 plant groups due to isotopic fractionation differences between their photosynthesis pathways (Meyers and Lallier-Vergès, 1999). It is difficult to differentiate the $\delta^{13}\text{C}_{\text{org}}$ signature between algal and C3 plants when lake and atmospheric CO_2 are at equilibrium (both typically range between -30 to -25 ‰), but C4 plants have more positive isotopic values with a range between -14 and -10 ‰. Interpreting $\delta^{15}\text{N}$ is complex because it is affected by organic matter source and available nitrogen in the water column and must be considered in conjunction with other productivity proxies, such as C:N and $\delta^{13}\text{C}_{\text{org}}$ (Meyers and Lallier-Vergès, 1999; Talbot, 2002). C3 land plants typically have an average $\delta^{15}\text{N}$ of 1 ‰ while phytoplankton have an average $\delta^{15}\text{N}$ of 8 ‰. Because total organic matter can be derived from both terrestrial and aquatic sources, the ratio of elemental organic carbon to total nitrogen (C:N) provides useful information about changes in the sources of organic matter to lacustrine systems. C:N values under 10 indicate aquatic sourced organic matter, typically algae, while values greater than 15 are indicative of C3 and C4 land plants (Meyers and Lallier-Vergès, 1999).

4.3.7 Lipid Biomarker Extraction & $\delta^2\text{H}$ Analysis

Lipids were extracted from a sub-set of thirty-five samples from the composite sediment core at the Lamont-Doherty Earth Observatory, Columbia University. Lipids were extracted from freeze-dried and homogenized sediments with dichloromethane and methanol solvent (9:1) using a Dionex Accelerated Solvent Extractor – 350. The total lipids extract was separated into aliphatic, ketone, and polar fractions through subsequent elutions using hexane, dichloromethane, and methanol solvent across a silica gel column

(70-230 mesh, 60A). The aliphatic fraction then underwent separation across a silver nitrate column (10 % AgNO₃) with hexane elution for *n*-alkanes and ethyl acetate elution for *n*-alkenes. The concentration of *n*-alkanes for each sample was determined using an Agilent Technologies 7890A gas chromatography mass spectrometer (GCMS).

The contribution of aquatic vs. terrestrial vegetation to the sediments was assessed using three indices. The average chain length (ACL) index quantifies the distribution of short vs. long chain *n*-alkanes with lower values (< 25) indicating aquatic vegetation and higher values (> 25) indicating terrestrial vegetation (Diefendorf et al., 2015; Mügler et al., 2008). The carbon preference index (CPI) represents the ratio of odd to even carbon atoms in leaf-wax *n*-alkanes with relative lows and highs indicating aquatic and terrestrial vegetation, respectively. The relative abundances of aquatic vs. terrestrial vegetation deposited in the lake was also assessed with the P_{aq} index, where higher values indicate greater abundance of aquatic plants (Ficken et al., 2000; Seki et al., 2009).

$$ACL = \frac{25[C25] + 27[C27] + 29[C29] + 31[C31] + 33[C33] + 35[C35] + 37[C37]}{[C25] + [C27] + [C29] + [C31] + [C33] + [C35] + [C37]}$$

$$CPI = \frac{([C23] + [C25] + [C27] + [C29] + [C31] + [C33] + [C35]) + ([C25] + [C27] + [C29] + [C31] + [C33] + [C35] + [C37])}{2 \times ([C24] + [C26] + [C28] + [C30] + [C32] + [C34] + [C36])}$$

$$P_{aq} = \frac{[C23] + [C25]}{[C23] + [C25] + [C29] + [C31]}$$

Twenty long-chain *n*-alkane extract samples then underwent hydrogen isotopic analysis (δ²H). δ²H measurements of the *n*-alkanes were made using a combined Thermo Scientific Trace GC Ultra GCMS and Delta V Plus IRMS (GC column: 30m, 0.25mm, 14.2psi, 60 °C). Samples were run with an isotopic standard (Mix A7) and a lab standard to assess drift. Raw isotopic values underwent drift correction using MATLAB. Isotopic variability ranged between 3.5-4.5 % for samples (Polissar and D'Andrea, 2014). Measurements are reported in delta notation as per mil (‰) with measurements relative to the VSMOW (Vienna Standard Mean Ocean Water). The average chain length (ACL),

carbon preference index (CPI), and aquatic vegetation index (P_{aq}) were calculated to assess changes in the distribution of *n*-alkanes and assess whether they were sourced by aquatic or terrestrial vegetation (Diefendorf et al., 2015; Ficken et al., 2000; Marzi et al., 1993).

Hydrogen isotopic measurements of the short-chain *n*-alkane nC_{23} reflects the isotopic composition of the lake water in which aquatic plants grow. The isotopic composition of lake water in turn incorporates changes in the isotopic composition of inflows (primarily precipitation) and subsequent modification from evaporation (Mügler et al., 2008). The isotopic measurements of longer chain *n*-alkanes (e.g., nC_{29} and nC_{31}) incorporate the isotopic signature of soil water, which closely tracks the isotopic composition of precipitation.

4.4 Results

4.4.1 Core Description

A 294-cm-long composite core was constructed using the E-15 surface and D-15 Livingstone cores. The composite core was differentiated into two distinct halves based on visual stratigraphy (Fig. 4.4). The bottom 144 cm of the core from 294 to 150 cm consisted of a light brown peat material with bands of white coarse sand and gravel between 283-280 cm and 270-265 cm and a tan sand layer from 220-215 cm. The top 150 cm of the core consisted of massive units of dark to light brown muds with interspersed fragments of organic matter, including charcoal and grasses. There were two distinct white clay bands between 125-120 cm and 145-142 cm.

4.4.2 Age Model

Excess ^{210}Pb activity was highest at the top of the E-15 core, peaking at 10 cm, before decaying to background levels at 32 cm (Table 4.1; Fig. 4.5). An age model was developed for the top 31.25 ± 0.25 cm based on the constant rate of supply (Appleby and Oldfield, 1978). Three samples had ^{137}Cs activity at 14.75, 16.25, and 23.75 ± 0.25 cm depth, which were dated to -38 ± 3.4 , -34 ± 3.8 , and -3 ± 5.6 BP. The oldest ^{210}Pb date was at 31 cm depth and dated as 67.3 ± 13 BP. Eight radiocarbon dates (Table 4.2) were

obtained from charcoal fragments and calibrated using the IntCal 13 dataset (Reimer et al., 2013) using the program Bacon (Blaauw and Christen, 2011). The oldest ^{14}C date for D-15 at 271-269 cm was calibrated to 11.27 ka. Dates below this depth were extrapolated by extending the age model in Bacon. The ^{210}Pb and ^{14}C dates were used to assess the age-depth relationship and an age model was established using the Bacon program spanning the last 12.3 ka (Fig. 4.6). The full age model dataset is in Appendix 3, Table A 3.1.

4.4.3 Organic Matter Chemistry

Total organic matter was highest during the early Holocene (11.7 – 6.2 ka) averaging 44.5% until 6.2 ka (Fig. 4.7A). Total organic matter subsequently decreased throughout the end of the middle (5 – 3 ka; average: 33 %) and late Holocene (3 ka to present; average 27.4 %). Total carbonate was low throughout the record (3.0 %) with a few isolated high carbonate intervals (17.7-34 %) from 11 – 10.9 ka (Fig. 4.7B).

The ratio of elemental organic carbon to total nitrogen (C:N) ranged between 8.6 and 28.1 with an average of 11.5 in the record (Fig. 4.7C). C:N was elevated during the early Holocene from 11.7 to 9.3 ka (average: 14.87) and slowly decreased from 9.3 to 6 ka (average: 12.13), suggesting a greater contribution of organic matter from terrestrial plants to the lake. After 6.0 ka, C:N was consistently lower for the rest of the record (average: 10.13).

Organic matter $\delta^{13}\text{C}_{\text{org}}$ at Galang Co varied significantly during the Holocene with $\delta^{13}\text{C}$ values averaging -27.2 ‰ and ranging between -32.41 ‰ to -12.4 ‰ (Fig. 4.7D). The most positive values of $\delta^{13}\text{C}_{\text{org}}$ occurred during the early Holocene between 11.9 – 11 ka (average: -21.59 ‰). After 11 ka, $\delta^{13}\text{C}_{\text{org}}$ varied between -29 and -25 ‰ before decreasing to an average -30.2 ‰ over the last 1 ka.

Galang Co sedimentary $\delta^{15}\text{N}$ averaged 0.99 ‰ and ranged between -1.25 ‰ and 2.37 ‰ throughout the record (Fig. 4.7E). $\delta^{15}\text{N}$ ranged between -1 and 0.5 ‰ between 11.3 – 6.2 ka. After 6.2 ka, $\delta^{15}\text{N}$ increased by 1.7 ‰ and varied between 0.6 to 2.4 ‰ (average: 1.8 ‰), remaining elevated until 1 ka, at which point $\delta^{15}\text{N}$ decreased to 0.9 ‰.

4.4.4 Sedimentology & Magnetic Susceptibility

Dry bulk density was variable throughout the record, averaging 0.2 g cm^{-3} , with lower values during the early Holocene (11.7 – 9.1 ka; Fig. 4.8A). MS was low, averaging $1.3 \text{ SI} \times 10^{-5} \text{ SI}$, until 6.2 ka before increasing to an average of $12.16 \text{ SI} \times 10^{-5} \text{ SI}$ over the last 6 ka (Fig. 4.8B). Percent lithics varied during the Holocene (average: 51.9 %; range: 0.7-98 %) with low lithics between 11.7 – 11 ka and 7.5 – 6.5 ka corresponding to high organic matter (Fig. 4.8C). Lithics were higher from 6.5 ka to present (average: 60.1 %; range: 1.1-98 %) corresponding with finer sediments.

Clay content was low from 11.7 to 6 ka (average: 4.33 %; range: <0.1-18.5 %) before increasing and remaining high over the last 6 ka (average: 6.73 %; range: 0.2-35.3 %; Fig. 4.8D). Silt (average: 51.7 %; range: <0.1-86.1 %) and sand (average: 42.8 %; range: <0.1-100 %) abundances showed an inverse relationship throughout the Holocene (Fig. 4.8E and 4.8F). Silt content was lowest in the early Holocene from 11.7 to 6 ka, averaging 45%, before increasing around 6 ka to an average of 58.4 % when there was a noticeable change towards finer sediments in the core lithology. Percent sand was highest from 11.7 to 6 ka during the early Holocene averaging 50.6 % and declined after 6 ka by 15.7 %. Grain size diameters shows an abundance of coarser sediments from 11.7 until around 6 ka, when grain size distribution shifted to finer sediments for the rest of the Holocene (Fig. 4.8G).

4.4.5 XRF Geochemistry

Of the forty-seven elements measured on the composite core using XRF, I focus on iron, manganese, titanium, and zirconium for hydroclimatic interpretations. Titanium (Ti) and Zirconium (Zr) are conservative elements typically associated with clastic detritus, where higher Ti is interpreted as representing more terrestrial sediments being deposited into the lake, and vice versa (Croudace et al., 2006). Measurements of Ti (range: 701-113,073 cps) were lower in the early Holocene, averaging 13,226 cps from 11.7 to 6 ka (Fig. 4.9A). Ti concentrations increased after 6 ka, averaging 17,940 cps, indicating an increase in terrestrial sediments being deposited into the lake. Zr (range: 0-

3413 cps) follows a similar pattern with Ti, with lower Zr from 11.7 to 6 ka, averaging 959 cps (Fig. 4.9C). Zr increased after 6 ka, averaging 1485 cps.

Iron (Fe) is also linked with clastic material, but this relationship is additionally influenced by the lake's redox potential, with Fe staying in solution under anoxic conditions because it is redox sensitive (Cuven et al., 2010; Nesbitt and Markovics, 1997). Fe content showed a significant transition from low measurements, average 68,188 cps, between 11.7 and 6 ka and subsequent higher values in the rest of the record after 6 ka, averaging 159,015 cps (Fig. 4.9B). Redox potential of the lake was inferred by the ratio of manganese (Mn) to Fe (Naehler et al., 2013). The Mn: Fe ratio was higher between 11.7 and 6 ka, averaging 0.052, than declined after 6 ka to an average of 0.025 (Fig. 4.9D). The full XRF dataset is in Appendix 4, Tables A 4.1 – 4.6.

4.4.6 δ^2H Lipid Biomarkers

Long-chain *n*-alkanes (e.g., nC29 and nC31) are typically produced by terrestrial vascular plants while short chain *n*-alkanes (e.g., nC23) are generally produced by emergent and submerged aquatic macrophytes (Ficken et al., 2000; Seki et al., 2009). Mid-chain *n*-alkanes (e.g., nC25) can reflect a mixture of aquatic and terrestrial vegetation sources (Mügler et al., 2008; Seki et al., 2009). Overall the concentration of *n*-alkanes varied with the highest concentrations in the mid-chain *n*-alkanes nC25 (average: 6094 ng/g) and nC27 (average: 5913 ng/g), and with lower concentrations in short-chain and long-chain *n*-alkanes: nC23 (average: 3847 ng/g), nC29 (average: 4869 ng/g), and nC31 (average: 2528 ng/g; Fig 4.10). The concentration of leaf-wax *n*-alkanes in general were low for most of the Holocene before an increase in the concentrations of nC23-nC29 around 1.7 ka and subsequent decline (Fig. 4.10A-D). The concentration of nC31 was high between 11.7-8 ka before decreasing and remaining low throughout the remainder of the Holocene (Fig. 4.10E).

The ACL at Galang Co averaged 27.7 throughout the Holocene with values between 26.9 and 28.6, indicating that aquatic vegetation dominated the record (Fig. 4.10F). The CPI was highly variable over the record, ranging from 1.9 to 9 (average: 5.5), with higher CPI during the first half of the record from 12 to 5 ka, suggesting a higher abundance of terrestrial vegetation (Fig. 4.10G). P_{aq} was high for most of the record,

varying between 0.28 and 0.69 and averaging 0.5 indicating a high contribution of aquatic vegetation to the lake (Fig. 4.10H).

The concentration of sedimentary *n*-alkanes was generally low throughout the Galang Co core, limiting $\delta^2\text{H}$ measurements to twenty of the thirty-five samples selected. $\Delta^2\text{H}$ isotopic measurements on short-chain and long-chain *n*-alkanes ranged from -243.1 ‰ to -156.3 ‰ (Fig. 4.11). $\delta^2\text{H}_{\text{C}_{23}}$ was higher from 10.7 – 7.7 ka, averaging -192.2 ‰, then decreased by 18 ‰ during the middle Holocene (6 – 2.5 ka) to 174.2 ‰ (Fig. 4.11A). After 2.5 ka, $\delta^2\text{H}_{\text{C}_{23}}$ increased by 43.3 ‰ to an average of -167.4 ‰. Both $\delta^2\text{H}_{\text{C}_{25}}$ and $\delta^2\text{H}_{\text{C}_{27}}$ averaged -215.8 and -218.8 ‰ during the early Holocene (10.7 – 7.7 ka), increased during the middle Holocene (6 – 2.5 ka) by 21.1 ‰ and 12.6 ‰ for averages of -194.7 ‰ and -206.2 ‰ respectively and subsequently decreased from 2.5 ka to present (Fig. 4.11B and 4.11C). Both long-chain *n*-alkanes $\delta^2\text{H}_{\text{C}_{29}}$ and $\delta^2\text{H}_{\text{C}_{31}}$ were lower during the early Holocene from 10.7 – 7.7 ka, averaging -230.1 and -223.8 ‰ (Fig. 4.11D and 4.11E). $\delta^2\text{H}_{\text{C}_{29}}$ decreased by -13.1 ‰ at 5.6 ka then subsequently increased and remained higher throughout the middle and late Holocene, averaging -222.7 ‰ from 5.3 ka to present. $\Delta^2\text{H}_{\text{C}_{31}}$ record is limited after 7 ka with few data points, increasing to an average of -217.1 ‰ from 2.7 ka to present.

4.5 Discussion

4.5.1 Holocene Hydroclimate & Lake Level Variability at Galang Co

The co-occurrence of peat, high C:N, low $\delta^{15}\text{N}$, high $\delta^{13}\text{C}_{\text{org}}$, and coarse grain sizes at Galang Co between 11.7 and 6.2 ka strongly suggests that water levels were at a minimum during the early and middle Holocene. High organic matter inputs to the lake between 11.7 to 6.2 ka, which coincides with low $\delta^{15}\text{N}$, high C:N, and high $\delta^{13}\text{C}_{\text{org}}$, all suggest high influxes of terrestrial vegetation (C3 and C4 plants) to the lake. Shallow lake conditions are additionally supported by high Mn:Fe ratios from 11.7 to 6.2 ka, which indicate oxygen-rich conditions during this time, with shallow waters being more oxygen-rich than deeper waters. The onset of deeper lake conditions between 7 and 6 ka is suggested by rapid changes in sedimentology, including a transition to finer sediments and greater aquatic productivity as indicated by higher $\delta^{15}\text{N}$ and C:N values below 10.

Anoxic conditions as evident with lower Mn:Fe from 6.2 ka to present, indicate deeper lake conditions at Galang Co were established in the middle Holocene and have persisted through the present day.

The short-chain *n*-alkane $\delta^2\text{H}_{\text{C}_{23}}$ results support the Galang Co lake level interpretations based on sedimentological and geochemical data. Specifically, high (low) $\delta^2\text{H}$ values of nC_{23} correspond to lower (deeper) lake levels. $\delta^2\text{H}_{\text{C}_{23}}$ was high during the early Holocene from 11 to 7.7 ka, indicating increased evaporation when lake levels were low as indicated by peat-rich, coarse sediments. $\delta^2\text{H}_{\text{C}_{23}}$ decreased in the middle Holocene (6 – 2 ka) as the lake transitioned to a deeper steady-state as indicated by the predominance of fine-grained sediments and high aquatic productivity. Based on this relationship, I interpret $\delta^2\text{H}_{\text{C}_{23}}$ as a signal of effective moisture at Galang Co. Stronger ISM intensity, inferred by long-chain *n*-alkane $\delta^2\text{H}_{\text{C}_{29}}$ and $\delta^2\text{H}_{\text{C}_{31}}$, persisted in the early Holocene (11 – 6 ka) when effective moisture was lowest, likely as a result of high evaporation. Both evaporation and monsoon intensity decreased in the middle Holocene around 6 ka resulting in greater effective moisture that persisted until the late Holocene when effective moisture declined around 1.5 ka. This relationship between monsoon precipitation, effective moisture, and lake levels at Galang Co stands in contrast to many of the existing records from the Tibetan Plateau, but as is discussed below, is not incompatible with the well-established Holocene trend of the ISM.

The Galang Co local hydroclimate record stands in sharp contrast to many of the ISM and lake level reconstructions from other sites on the Tibetan Plateau, which indicate greater effective moisture and deeper lake levels during the early Holocene (11 – 7 ka) when the ISM was strengthened, followed by a decline in effective moisture in the middle Holocene (7 – 3 ka) as the ISM weakened. This trend is evident at Paru Co (29.8°N, 92.4°E, 4845 m a.s.l.), a shallow high altitude lake approximately 300 km west of Galang Co, where high effective moisture and deeper lake levels are evident in the early Holocene (Bird et al., 2014). High %lithics and %sand, inferred as runoff and lake level signals respectively, indicate that effective moisture remained high until at least 7 ka when runoff declined while lake levels didn't fall until 5 ka (Fig. 4.12G-H).

An effective moisture and temperature record at Koucha Lake in eastern Tibet (34.0°N, 97.2°E, 4540 m a.s.l.), located 400 km northeast of Galang Co, shows a

maximum in effective moisture in the early Holocene (11.7 – 6 ka) simultaneous with warmer temperatures indicated by a steppe dominated plant community (Herzschuh et al., 2009). The warmer, wetter Tibetan Plateau during the early Holocene is also evident in the Lake Zigetang pollen record (90.9°E 32.0°N), where warmer temperatures persisted until 5 ka, when the climate transitioned to cooler and drier conditions (Herzschuh et al., 2006). High effective moisture derived from the pollen record coincided with lower carbonate $\delta^{18}\text{O}$ in the sediments from Koucha Lake between 11.7 – 7 ka, indicating lower lake levels (Mischke et al., 2008). Colder temperatures and drier conditions became dominant after 6 ka, evidenced by a transition to a high-alpine meadow vegetation community, and coincides with deeper lake levels inferred from higher $\delta^{18}\text{O}$. The contradiction between high effective moisture in the watershed and lower lake levels at Koucha Lake indicates is suggested to be an indication that high evaporation impacted lake levels even as the local hydroclimate was warmer and wetter.

The sharp contrast between Galang Co and other monsoon records is also evident when compared with records across the broader ISM extent. The timing of the transition to a deeper lake at Galang Co around 6.2 ka coincides with declining monsoon intensity at Dongge, Mawmluh, and Qunf Caves (Fig. 4.13C-E). Mawmluh Cave in northeastern India (25.3°N, 91.9°E, 1290 m a.s.l.), supports a strong monsoon in the early Holocene, with depleted $\delta^{18}\text{O}$ between 8 to 6 ka (Berkelhammer et al., 2012). Monsoon intensity subsequently declined after 6 ka with a hiatus in the record after 3.5 ka, interpreted as a significant reduction in effective moisture. Another $\delta^{18}\text{O}$ record from Dongge Cave (25.3°N, 108.1°E, 680 m a.s.l.), located in southeastern China, also shows a strengthened monsoon from 11-5 ka (Dykoski et al., 2005). The Dongge Cave is at the farthest east extent of the ISM and follows the same precipitation patterns as other ISM records, with a stronger monsoon during the early Holocene with a noted decline towards weaker monsoon conditions after 5 ka. These cave records indicate that monsoon intensity and effective moisture was greatest in the early Holocene and declined between 6 and 5 ka when solar insolation declined and the ITCZ shifted southward (Fleitmann et al., 2003).

4.5.2 Hydroclimate Drivers of Galang Co Effective Moisture

I hypothesize that low effective moisture in the Galang Co record is attributed to local hydroclimate conditions. Whatever mechanism is responsible for the hydroclimate response at Galang Co, a reversal of this condition must have occurred around the mid-Holocene decline in the monsoon resulting in a deeper lake. The timing of the transition from a shallow to a deep lake at Galang Co occurs at the same time as monsoon intensity declines in other records, supporting the conclusion that hydroclimate is the driver of effective moisture and lake levels at Galang rather than other hydrological factors. Strong monsoon conditions in the early Holocene (11.7 to 7 ka) at ISM sites were driven by broader climate mechanisms, including higher solar insolation, the position of the ITCZ, and a La Niña-state in the Pacific (Berkelhammer et al., 2012; Bird et al., 2014; Emile-Geay and Tingley, 2016; Emile-Geay et al., 2016; Fleitmann et al., 2003).

However, I propose that the more likely mechanism is evaporation driven by temperatures and ice cover. The early Holocene was warmer as observed in the Koucha Lake and Lake Zigetang pollen records which could have resulted in reduced ice cover on the lake. Ice plays an important role in reducing evaporation from a lake surface during the winter season, with modern studies of Tibetan Plateau lakes indicating that ice cover results in lower evaporation and greater lake levels (Lazhu et al., 2016; Lei et al., n.d.). Evaporation on Plateau lakes is highest during the fall and winter due to the large temperature differences between the lake water and air (Lei et al., n.d.), providing further evidence that a decline in ice cover on Galang could be responsible for the anti-phase effective moisture pattern observed in the early and middle Holocene. An ice free Galang Co would have allowed for year-round evaporation driving a reduction in effective moisture and decreasing lake levels. Evaporation rates in the early Holocene would have been higher due to warmer temperatures and could account for low lake levels if Galang Co had little or no ice cover during the year. When temperatures cooled on the Plateau during the middle Holocene between 6 and 5 ka, winter ice cover would have been reestablished and could reduce the evaporation season on the lake by up to six months, resulting in higher effective moisture and lake levels. Another possible driver of the effective moisture trends at Galang Co is a rainout or orographic effect with high convection in the early Holocene resulting in rainout along southern slopes in the

Himalayas and southern Tibet. When monsoon intensity and, subsequently, convection declined, moisture remained in the atmosphere longer, reaching low altitude inter-montane valleys in the eastern plateau. The inter-montane valley where Galang is situated is flanked by high elevation mountains in three-directions, to the east, west and south, which could prevent moisture from reaching the site during high convection and may be responsible for the contradictory moisture record at this site. Further research is needed to determine which mechanism is responsible and requires the development of additional records from this region, including low-elevation sites, to see if this phenomenon is unique to Galang Co.

4.5.3 Elevation-Dependent Expression of Monsoon Precipitation

As I hypothesized, Galang Co is an effective moisture record of the southeastern Tibetan Plateau, which shows that the early Holocene (11.7 – 7 ka) was extremely evaporative (low P:E balance). Evaporation began to decline between 7 and 6 ka, after which effective moisture increased (higher P:E balance). The middle Holocene transition in lake conditions at Galang Co from 7 to 6 ka coincides with shift towards a global weaker monsoon and cooler Northern Hemisphere temperatures. Solar insolation, a driver of the decline in monsoon intensity, declined after reaching an early Holocene maximum, and steadily decreased through the middle and late Holocene (Berger and Loutre, 1991). Lower solar insolation is a driving force of the southerly shift of the ITCZ, weaker monsoon winds, and more El Niño-like conditions in the Pacific. An ITCZ record at Qunf Cave in southern Oman (17.2°N, 54.3°E, 650 m a.s.l.), also supports stronger monsoon intensity from 10 – 6 ka with depleted $\delta^{18}\text{O}$ during this period indicating a more northerly ITCZ position (Fleitmann et al., 2003). After 6 ka, the ITCZ moved further south as evidenced by increasing $\delta^{18}\text{O}$ at Qunf Cave, where a hiatus in the record from 2.7 to 1.3 ka coincides with reduced ISM winds in the Arabian Sea (Gupta et al., 2003). Pacific sea surface temperatures (SSTs) from the eastern Pacific near the Baja Peninsula (Marchitto et al., 2010), Laguna Pallcacocha (Moy et al., 2002), and the sand record at El Junco (Conroy et al., 2008) indicate a La Niña-like state in the Pacific between 11.7 – 6 ka before a transition to more frequent El Niño-like conditions from 6 ka to present. The timing of the state-change in these ISM drivers, support our hypothesis that the transition

to a wetter local hydroclimate at Galang Co is the result of a climatic change rather than local hydrological change.

As a low-elevation site on the Tibetan Plateau, Galang Co exhibits a strong local hydroclimate response to the decline in ISM precipitation, however, the lake level interpretation shows an anti-phase response to other high elevation records. A lack of low-elevation paleoclimate records from the region has limited our understanding of monsoon expression in low-elevation areas of the Tibetan Plateau, increasing the importance of the interpretation of the Galang Co record. I have hypothesized that this anti-phase lake level relationship is the result of high evaporation in the early Holocene driven by warmer temperatures and reduced ice coverage. Lower lake levels, despite higher precipitation, in the early Holocene suggests that local hydroclimate at low-elevation sites is driven by evaporation.

The anti-phase trend of high precipitation and low lake levels, was also observed at Koucha Lake, where the pollen record indicated high effective moisture and warmer temperatures, while the carbonate sediment record shows low lake levels (Herzschuh et al., 2009; Mischke et al., 2008). Both Galang Co and Koucha Lake were evaporation-controlled lakes, exhibiting lower lake levels despite higher monsoon precipitation in the warmer, early Holocene. Lakes are more susceptible to evaporation, as the lake experiences year-round evaporation, while the vegetation community is largely dormant during the driest parts of the year. As the monsoon coincides with the growing season, plant communities are reflective of trends in the ISM, with pollen and long-chain *n*-alkane proxies being minimally affected by evaporation. The seasonality of the pollen record at Koucha Lake and the long-chain *n*-alkane record ($\delta^2\text{H}_{\text{C}29}$ and $\delta^2\text{H}_{\text{C}31}$) at Galang Co is the most likely explanation for indicators of high early Holocene ISM precipitation in the respective watersheds, while lower lake levels persisted. Projections of warmer temperatures on the Tibetan Plateau with climate change indicate that southeastern Tibetan Plateau will become drier, as evaporation increases, ice cover decreases, and other moisture sources, such as glacial melt, decrease (Yao et al., 2007; Yao et al., 2012). Lakes, like Galang Co, may be more strongly impacted by these changes, with greater evaporation occurring during the fall and winter months, that would be exacerbated by reduction in ice cover. The Galang Co Holocene ISM interpretation suggests that as air

temperatures continue to warm on the Tibetan Plateau, evaporation rates will play a larger role in determining water availability.

4.6 Conclusions

Galang Co demonstrates a unique contradiction to other ISM paleoclimate records from the Tibetan Plateau, with a shallow lake during the ISM maximum from 11.7 to 6.2 ka and a deeper lake after monsoon intensity declined after 6.2 ka. Rising lake levels at Galang Co from 7 – 6.2 ka coincide with the gradual weakening of the mid-Holocene monsoon at other sites, evidenced by falling lake levels at Paru Co and higher $\delta^{18}\text{O}$ at Dongge, Mawmluh, and Qunf Caves. The concurrent timing of the change in lake levels at Galang Co with declining ISM intensity at other sites from the Tibetan Plateau suggest that shifts in effective moisture at Galang Co was driven by broader climate forcing. This inverse relationship between ISM precipitation and effective moisture indicate that Galang Co was an extremely evaporative environment during the early Holocene and that evaporation declined after 6.2 ka. I suggest that ice cover drove this change, with warmer temperatures in the early Holocene resulting in limited ice cover on Galang Co and year-round evaporation. During the middle Holocene, temperatures on the Tibetan Plateau declined, increasing ice coverage on the lake and reducing evaporation. A lack of low-elevation sites on the Tibetan Plateau limits our ability to confirm whether the lake level responses at Galang Co to synoptic ISM intensity is consistent with other sites or is driven by local conditions. New records are needed both at low-elevation sites and in the easternmost extent of the ISM on the Tibetan Plateau to determine the mechanisms responsible for Galang Co's low lake stand during a strong monsoon. The Galang Co record suggests that low-elevation lakes in the southeastern Tibetan Plateau are vulnerable to high evaporation when temperatures increase that can drive lower lake levels despite increased precipitation, indicating that climate change can have a significant impact on water availability in this highly populated region.

4.8 Figures

Figure 4.1. Paleoclimate archives from the greater ISM region including Galang Co (GAL; red), Paru Co (PC), Mawmluh Cave (MA); Dongge Cave (DC), Qunf Cave (QC), Arabian Sea (AS), Eastern Pacific (EP), and El Junco (EJ). Lake and marine sediments are marked with circles and stars respectively. Cave records are marked with squares. The Qamdo weather station (QA) is marked with an open circle.

Figure 4.2. Galang Co (blue outline) and its watershed relative to the Parlang Zangbo River and surrounding region (A). Galang Co and its surrounding shoreline with the modified inlet on the southwest corner of the lake and the outlet on the southeast (B). On the lake, locations of core sites are marked with red circles while the surface sediments and soil samples are marked with blue circles.

Figure 4.3. Thirty-year average of monthly total precipitation (mm \pm s.d.) and average temperature ($^{\circ}$ C \pm s.d.) at Qamdo weather station.

Figure 4.4. Stratigraphy of the composite Galang Co E-17 surface and D-17 Livingstone core. Core lithological units have been colored and marked to include clay (dashed lines), mud (silt and clay; horizontal lines), sand (small dots), gravel (large dots), and peat (solid grey). The location of radiocarbon dated material are designated with triangles.

Figure 4.5. Supported (grey) and excess (blue) ^{210}Pb activity (± 1 s.e.m.) and ^{137}Cs activity (gray bar) from the top 35 cm of the E-17 surface core.

Figure 4.6. Age model for Galang Co composite E-17 and D-17 core over the past 12.3 ka using both ^{210}Pb and ^{14}C dates.

Figure 4.7. Sedimentology and geochemistry of Galang Co E-17 and D-17 composite core including total organic matter (TOM %; A) and total carbonates (TC %; B) as derived from loss-on-ignition and the ratio of elemental carbon to nitrogen (C: N; C), organic matter $\delta^{13}\text{C}$ (VPDB ‰; D), and sediment $\delta^{15}\text{N}$ (air ‰; E). Black vertical lines denote average values over the record. Red and blue backgrounds indicate shallow and deeper lake conditions respectively.

Figure 4.8. Physical sedimentology of Galang Co E-17 and D-17 composite core including dry bulk density (BD g x cm^{-3} ; A), wet sediment magnetic susceptibility (MS $\text{SI x } 10^{-5}$), 5 point moving average (MA) percent total lithics I, percent clay 5 pt. MA (D), percent silt 5 pt. MA I, percent sand 5 pt. MA (F), and a histogram of grain size diameters (G). Black vertical lines denote average values over the record. Red and blue backgrounds indicate shallow and deeper lake conditions respectively.

Figure 4.9. Select elemental XRF results from Galang Co E-17 and D-17 composite core including Ti (A), Fe (B), and Zr (C) and the ratios of Mn: Fe (F). All measurements are in counts per second (cps). Black vertical lines represent average values over the record. Red and blue backgrounds indicate shallow and deeper lake conditions respectively.

Figure 4.10. The concentration of Galang sediment *n*-alkanes (ng/g) for nC23 (A), nC25 (B), nC27 (C), nC29 (D), and nC31 I carbon chain lengths. The average chain length (ACL; F), carbon preference index (CPI; G), and aquatic vegetation index (P_{aq} ; H) of sediment *n*-alkanes. Black vertical lines denote average values over the record. Red and blue backgrounds indicate shallow and deeper lake conditions respectively.

Figure 4.11. Galang E-17 and D-17 composite core sediment $\delta^2\text{H}$ (‰) for nC23 (A), nC25 (B), nC27 (C), nC29 (D), and nC31 (E) carbon chain lengths. Black vertical lines denote average values over the record. Red and blue backgrounds indicate shallow and deeper lake conditions respectively.

Figure 4.12. Galang Co $\delta^{15}\text{N}$ (‰; A), ratio of C to N (B), $\delta^2\text{H}_{\text{c23}}$ (C), percent silt 5 pt. MA (D), percent sand 5 pt. MA (E) in conjunction with the reconstruction of effective moisture from Koucha Lake (F), the sand and lithics records from Paru Co (%; G-H), and temperature reconstruction from Lake Zigetang. Grey background indicates period of low lake level in Galang Co (12.5-6 ka). Average values over the record are designated as vertical lines. Red and blue backgrounds indicate shallow and deeper lake conditions respectively.

Figure 4.13. Galang Co sand 5 pt. MA (%; A) and $\delta^2\text{H}_{\text{c23}}$ (‰; B) compared with records from the broader ISM extent, the East Asian Monsoon, and the El Niño-Southern Oscillation. Records include Dongge Cave $\delta^{18}\text{O}$ (‰; C), Mawmluh Cave $\delta^{18}\text{O}$ (‰; D), Qunf Cave $\delta^{18}\text{O}$ (‰; E), Eastern Pacific SSTs (°C; F), El Junco sand (%; G), and Pallacocha (red color intensity). Grey background represents low lake level stand (12.5-6 ka) at Galang Co. Vertical lines denotes average values over each record. Red and blue backgrounds indicate shallow and deeper lake conditions respectively.

5. CONCLUSIONS

This dissertation provides three high-resolution paleoclimate records of Holocene (11.7 ka to present) Indian summer monsoon (ISM) expression in Tibet. Sediments from three small lakes, Nir'Pa Co, Cuobu, and Galang Co, situated along an east-west transect on the southeastern Tibetan Plateau address knowledge gaps of the spatial and temporal patterns of monsoon precipitation and local hydroclimate conditions in connection with broader regional and global climate drivers. Nir'Pa Co is a late Holocene, leaf wax *n*-alkane hydrogen isotopes ($\delta^2\text{H}$) hydroclimate record (chapter 2), Cuobu is a 8.3 ka record of effective moisture, runoff, and leaf wax *n*-alkane $\delta^2\text{H}$ hydroclimate (chapter 3), and Galang Co is a lower-elevation effective moisture and lake level record for the entire Holocene (chapter 4). Each record uses a combination of sedimentological (*i.e.*, grain size, total organic matter), geochemical (*i.e.*, XRF), and isotopic proxies (*i.e.*, leaf-wax *n*-alkanes hydrogen ($\delta^2\text{H}$), organic carbon ($\delta^{13}\text{C}$), and nitrogen ($\delta^{15}\text{N}$)) to characterize local and synoptic hydroclimate conditions on centennial and millennial time scales.

Synoptic hydroclimate, inferred by long-chain *n*-alkane $\delta^2\text{H}$, is a measure of regional ISM precipitation signals and, as demonstrated in this dissertation, may not be reflective of local hydroclimate conditions. In contrast, local hydroclimate conditions including effective moisture, lake levels and runoff, inferred from short-chain *n*-alkane $\delta^2\text{H}$, $\Delta\delta^2\text{H}_{\text{C23-C31}}$, grain size, XRF, carbon and nitrogen isotopes, explain how the lake and its watershed responded to altered monsoon precipitation patterns. The use of leaf-wax *n*-alkane $\delta^2\text{H}$ was crucial to this work, as this proxy captures growing season precipitation and evaporation signals that occur simultaneous with the monsoon season. Long-chain *n*-alkanes captured precipitation isotopic signatures through terrestrial vegetation, while aquatic vegetation-derived short-chain *n*-alkanes reflected the precipitation and evaporation signals captured by lake water. This multi-proxy, high temporal resolution approach addressed questions about the relationship between local and synoptic hydroclimate indicators of changes in monsoon intensity with respect to 1) regional and global climate drivers and events and 2) local hydrological and elevation conditions.

All three paleoclimate records are consistent with the well-documented pattern of an ISM-maximum in the early Holocene that transitioned to a weaker monsoon in the

middle Holocene with weaker conditions continuing to the present, however, each record shows that local hydroclimate and monsoon expression is more complex on shorter time scales and can be greatly impacted by site specific geomorphology and hydrology. Both the Galang and Cuobu records show that the early Holocene, when the ISM is recognized at its strongest, there were distinct periods of dry conditions locally. Cuobu indicated that intense precipitation in the early Holocene resulted in greater hydrological connectivity, due to higher lake and river water levels. Meanwhile, an anti-phase relationship observed at Galang, between ISM precipitation and lake levels in the early Holocene, indicates that it is possible to have low lake levels, even with heavy precipitation, if evaporation rates reach an unknown threshold. The Nir'Pa Co late Holocene leaf-wax $\delta^2\text{H}$ record demonstrates that even as monsoon intensity was at its weakest during the Holocene, there were distinct periods of drought and pluvial (wet) conditions. These changes in late Holocene monsoon intensity do not appear to be connected with globally-recognized climate events, the Medieval Climate Anomaly (MCA) and the Little Ice Age (LIA). Instead, these changes may be attributed to other broader scale climate drivers, such as sea surface temperatures and land surface gradients.

The connection between synoptic and local hydroclimate indicators varied between records, dependent on the mechanisms responsible for local hydroclimate variability and the sensitivity of the lake system to precipitation changes. The Nir'Pa Co $\delta^2\text{H}$ and grain size records suggested that synoptic long-chain *n*-alkane $\delta^2\text{HC}_{31}$ showed earlier evidence of monsoon weakening than grain size-inferred lake levels. Just as in the other records, when local hydroclimate responded to the monsoon weakening, that response was abrupt, indicating some threshold when monsoon precipitation declines before lake level responds. Abrupt changes in local hydroclimate are also highly visible in the Cuobu and Galang grain size records, but for both of these lakes, the timing of variability in runoff and lake levels, respectively, is concurrent with synoptic shifts in ISM expression.

While this dissertation has addressed several questions about the expression of the Holocene ISM on the Tibetan Plateau, particularly in relation to synoptic and local hydroclimate, it has also shown where further research is needed. The Galang Co record showed an anti-phase effective moisture and ISM precipitation relationship, however,

limited records in the region and, particularly, in low-elevation sites prevents further analysis on determining whether ice cover changes in the early and middle Holocene drove this relationship. The grain size record at Cuobu interpreted as a river runoff signal, suggests that rivers on the Tibetan Plateau may have peaked during the early Holocene, altering hydrological connections. To determine whether these proposed mechanisms are correct and answer other questions about the ISM, additional high-resolution paleoclimate records from the Tibetan Plateau and the broader ISM region need to be developed, with an emphasis on greater spatial and elevation representation. Paleoclimate records remain a crucial tool for improving our understanding of this complex and vital monsoon system and how it will respond to changes in climate drivers.

CURRICULUM VITAE

Melanie Marie Perello

Education

December 2020 Doctor of Philosophy in **Applied Earth Sciences**

Indiana University degree, earned at Indiana University-Purdue University
Indianapolis (IUPUI), Indianapolis, IN

Dissertation: Reconstructing Holocene Indian Summer Monsoon

Variability using High Resolution Sediments from the Southeastern Tibet

Ph.D. Minor: Geographic Information Science

Advisor: Dr. Broxton Bird

June 2016 Master of Science in **Environmental Science and Policy**

Center for the Environment, Plymouth State University (PSU), NH

Master's Thesis: Linking the Effects of Land Use vs Climate Change on

Water Quality in Northern New England lakes (Defended May 2015)

Advisor: Dr. Lisa Doner

May 2013 Bachelor of Science in **Biology** with All-College Honors

Westminster College, New Wilmington, PA

Thesis: The Behavior of Silver Nanoparticles in a Freshwater Tritrophic
System

Advisor: Dr. Ann Throckmorton

Publications

Perello MM, Kane DD, Golnick P, Hughes MC, Thomas MA, Conroy JD. 2017. Effects
of local weather variation on water-column stratification and hypoxia in the
western, Sandusky and central basins of Lake Erie. *Water* 9(4): 279.

Bird B, Lei Y, **Perello M**, Polissar PJ, Yao T, Finney B, Bain D, Pompeani D, Thompson
LG. 2017. Late Holocene Indian summer monsoon variability revealed from a

3,300-year-long lake sediment record from Nir'pa Co, southeastern Tibet. The Holocene 27(4): 541-552.

Perello M, Simon TP, Thompson H, Kane D. 2014. Feeding ecology the invasive round goby, *Appolonia melanostomus* (Pallas 1811), in the Western basin of Lake Erie. Journal of Aquatic Invasions 10(4): 463-474.

Middleton S, **Perello M**, Simon TP 2013. Length-weight relationships of the Mimic Shiner *Notropis volucellus* (Cope 1865) in the Western Basin of Lake Erie. The Ohio Journal of Science, 112 (2): 44-50.

Perello M, Throckmorton A. 2013. Effects of direct and dietary exposure to silver nanoparticles on a tritrophic system. Proceedings of the National Conference for Undergraduate Research 2013: 117-124.

Relevant Research & Work Experience

2019 – pres. **NOAA Coastal Management Fellow**, Minnesota's Lake Superior Coastal Program, Minnesota Department of Natural Resources

2015 – 2019 **Graduate Research Assistant**, Department of Earth Sciences, IUPUI

2014- 2015 **Student Lab Supervisor**, Watershed Sensing Lab, PSU

2014 - 2015 **Graduate Assistant**, Pathways Project, PSU

2013 - 2015 **Graduate Research Assistant**, Center for the Environment, PSU

2013 **Field Technician**, Westminster College Field Station

2011 - 2013 **All-College Honors Program Honors Program**, Westminster College

2012 **Undergraduate Researcher**, F.T. Stone Laboratory, The Ohio State University

Teaching Experience

2018-2019 **Lab Instructor, Environmental Geology**, Department of Earth Sciences, IUPUI

2018 **Teacher's Assistant, Earth Materials**, Department of Earth Sciences, IUPUI

- 2015 **Graduate Co-Instructor, Environmental Science & Policy Capstone,**
Environmental Science & Policy Department, PSU
- 2013 **Teacher's Assistant, Molecular Genetics & Heredity Lab,** Biology
Department, Westminster College
- 2012 **Teacher's Assistant, Recombinant DNA & Biotechnology Lab,**
Biology Department, Westminster College

Community Involvement & Outreach Experience

- 2019 **Mentor,** Center for Earth and Environmental Science, IUPUI
- 2018 **Mentor,** Multidisciplinary Undergraduate Research Institute, IUPUI
- 2018 - 2019 **Earth Sciences Representative,** School of Science Multidisciplinary
Committee, IUPUI
- 2017 - 2020 **Graduate Student Representative,** Global Environmental Change
Section, American Geophysical Union
- 2015 **Student Researcher,** U.S. State Department Diplomacy Lab, Department
of Earth Sciences, IUPUI
- 2015 **Mentor,** K-12 Science Education Outreach, Environmental Science &
Policy Department, PSU
- 2015 **Workshop Assistant,** K-12 Science Education, Outreach, Center for the
Environment, PSU
- 2014 **Researcher,** Environmental Economics, Environmental Science & Policy
Department, PSU & The Nature Conservancy
- 2014 **Researcher,** Community Reports on Water Resources, Environmental
Science & Policy Department, PSU
- 2014 **Web Designer,** Community Outreach, Environmental Science & Policy
Department, PSU
- 2014 **Facilitator,** Community Forum, Plymouth NH
- 2011-2012 **Youth Mentor,** Transformers Robotics Program, Westminster College
- 2011-2013 **Scholar-in-Service to Pennsylvania,** AmeriCorps

Presentations

Perello, M, Bird, B, Lei, Y, Pollisar P, Thompson, L, Yao, T. 2018. Holocene Indian Summer Monsoon Across a Transect of Lakes in Southeastern Tibet. American Geophysical Union Fall Meeting, Washington DC.

Perello, M, Bird, B, Lei, Y, Pollisar P, Thompson, L, Yao, T. 2018. Holocene Monsoon Rainfall and Lake Levels in Galang Co, Southeastern Tibet. Geological Society of America Annual Meeting, Indianapolis IN.

Perello, M, Bird, B, Lei, Y, Pollisar P, Thompson, L, Yao, T. 2018. Inferred Holocene Monsoon Rainfall and Lake Levels in Eastern Tibet. Geological Society of America North-Central Section Meeting, Ames IA.

Perello, M, Bird, B, Lei, Y, Pollisar P, Thompson, L, Yao, T. 2017. Measuring Holocene Indian Summer Monsoon Precipitation through Lake Sedimentary Proxies, Eastern Tibet. American Geophysical Union Fall Meeting, New Orleans LA.

Perello, M, Smythe, R, Borre, L, Baumert, K, Weirich, C, Bartlett, S, Klug, J, Johnson, D, Kimirei, I, and Perillo, G. 2017. Differences and similarities in perceived threats to North American lakes by scientists, managers, and stakeholders. GLEON 19, Lake Mohonk NY.

Perello, M, Bird, B, Lei, Y, Pollisar P, Thompson, L, Yao, T. 2017. Changing Indian Summer Monsoon Intensity throughout the Holocene at Galang Co, Southeastern Tibet. GLEON 19, Lake Mohonk NY.

Perello, M, Bird, B, Lei Y, Pollisar, P, Thompson, L, Yao, T. 2017. Tracking Changes in Indian Summer Monsoon Intensity using Precipitation and Lake Level Proxies from Eastern Tibet. GSA North-East and North-Central Joint Meeting, Pittsburgh PA.

Perello, M, Bird, B, Lei Y, Yao T, Thompson, L. 2015. Monitoring the Indian Summer Monsoon using lake sediments in the Eastern Tibetan Plateau. GLEON 17, Chuncheon South Korea.

Professional Societies

2019-20 American Meteorological Society

2017-18 North American Lake Management Society

2016-20	American Geophysical Union
2016-20	International Paleolimnological Association
2014-20	Global Lakes Ecological Observation Network
2014-20	Geological Society of America
2014-15	International Phycological Society
2014-17	Phycological Society of America
2013-14	Ohio Academy of Science
2012-14	Association for the Sciences of Limnology and Oceanography

Academic Societies

2018-19	Earth Sciences Representative , School of Science Multidisciplinary Committee, IUPUI
2017-19	Preparing Future Faculty and Professionals (PFFP), IUPUI
2017-19	Earth Sciences Representative , Graduate Student Council, School of Science
2016-17	Representative , Graduate and Professional Student Government, IUPUI
2014-15	Graduate Research Society, PSU
2012-13	Member, Pi Sigma Pi, Westminster College
2010-13	President , Beta Beta Beta, Westminster College
2010-11	Member, Lambda Sigma, Westminster College
2009-13	Vice-President, Secretary , Omicron Kappa Sigma, Westminster College

Honors & Awards

2016	GSA NC Section Graduate Student Poster (Honorable Mention)
2013, 2014	Pamela Marrapese Keep NH Lakes Clear Scholarship, PSU
2012	Thomas V. and Margaret Mansell Scholarship, Westminster College
2012	Allen P. Splete Leadership and Service Award, Westminster College
2011, 2012	Nathan & E. Lucille Beerbower Frey Scholarship Biology Department Award, Westminster College
2010-2013	Dean's List, seven semesters, Westminster College
2009	Vance Honors Scholarship, Westminster College

Research Grants

2015	Sigma XI Grants in Aid of Research Grant
2015	GSA Graduate Student Research Grant
2015	Paul C. Silva Student Grant, International Phycological Society
2014	Student Research Advisory Council (SRAC) Student Research Grant, PSU
2012	Undergraduate Research Grant - Drinko Center for Experiential Learning, Westminster College
